The Etisha Mitchell Scientific Society: PROFESSOR ALVIN S. WHEELER 38

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE SCIENCE AND THE PRACTICAL PROBLEMS OF THE FUTURE¹

THE end of the world has long been a favorite subject of speculation. The ancients and our forefathers of the middle ages were pleased to imagine some sudden final disaster; as by fire. Science in our own day furnishes a basis for a more definite forecast. Sudden catastrophe is still by no means precluded, for astronomers have occasionally witnessed outbursts in other regions of the universe which may have produced profound changes throughout neighborhoods like our solar system and have brought to some tragic end life on planets like the earth.

With the development of the doctrine of energy has come the conviction of an end of the world; inevitable, as the death of the individual is inevitable. In neither case, however, is longevity to be regarded as necessarily beyond human control. Biologists are beginning to intimate, and it would seem with growing confidence, the possibility, remote but thinkable, of a considerable extension of the term of bodily life. Equally conceivable is it that the race, if it becomes sufficiently wise before old age overtakes it, may so modify and control the conditions of life as to greatly prolong its career.

We do not need to consider a conceivable end by cosmic catastrophe any more than

¹ Address of the retiring president of the American Association for the Advancement of Science, Baltimore, 1908.

the individual in estimating the number of years that he may reasonably hope to live would take into account death by lightning—were that the only death, he might look forward to a very long life. Neither need we consider the accuracy of the forecasts of the probable future of the sun any more than the individual takes into account probable geological and climatic changes as having any bearing on his own expectancy of life. The drama of human existence on the earth is a fleeting show when measured in terms of the duration of the sun. The exhaustion of our supply of fixed nitrogen, a contingency discussed some years ago by Sir William Crookes, and of our free oxygen which was more recently suggested by Lord Kelvin are factors that bring the question of the duration of human activity somewhat nearer home but they are still so remote as to be of no immediate practical importance. Other factors there are, however, that are not only immediate but rapidly becoming imminent and pressing.

At the recent conference on the conservation of resources which met at the White House at the invitation of the president of the United States notes of warning were sounded concerning the coming exhaustion of coal, wood, ores and soils. Whether or not we accept as exact the estimates furnished by experts on that impressive occasion, there is no doubt that we are approaching the end of our available resources and that the near future will have momentous problems to face.

Certain things are clear.

First. Unchecked wastefulness as exhibited, for example, in the extermination of the bison, in the destruction of forests, in the exhaustion of the soil, in the disappearance from our coasts and streams, that once teemed with fish, of this important source of food supply, in the pouring into the air of an incredible amount of unused

fuel from hundreds of thousands of coke ovens must cease or our ruthless exploitation will bring disaster on generations soon to come. The prevention of these and countless other manifestations of individual and corporate greed is a problem for the economist and the law-maker although they will scarcely succeed in its solution without calling science to their aid.

Second. Saving and thrift offer at best only a postponement of the day of distress. The end of our supplies of coal and petroleum must ultimately be reached. Forests may be renewed and the soil restored to its maximum fertility but the problem which is presently to confront the race is that of civilized existence without recourse to energy stored by the slow processes of nature. This problem must be definitely solved before the complete exhaustion of our inherited capital.

Third. The problem is not without conceivable solution, since the annual accession of energy from the sun, did we know how to utilize it without awaiting the slow processes of storage employed by nature, is ample for every thinkable need of the future inhabitants of our planet. Estimates of the constant of solar radiation show that about 2.18 kilowatts of power is continually received from the sun for every square meter of the earth's surface or over seven and a half millions of horsepower per square mile. The present use of power in the United States is about eighty million horse-power or one horse-power per capita. This quantity is likely to increase more rapidly than the population in the future unless curtailed by lack of fuel, but it is evident that a very small fraction of the sun's radiation would meet all demands.

Now abundant power is soon to be the factor upon which material advancement will chiefly depend. To obtain it in the

face of the disappearance of coal and petroleum will be imperative. For success in this, upon which in the immediate future the welfare of the race and ultimately its very perpetuity is to depend, we must look to science. Mere ingenuity or inventiveness, however widely developed, will not suffice. The inventor and the engineer can but utilize and apply the material which the man of science provides and with the exhaustion of our stores of scientific knowledge civilization must halt.

It is of this fundamental relation of science to the progress of our civilization that I wish to speak. The fact that material progress is based upon science seems to be but dimly understood. It appears to be generally supposed that it is to the inventor and to those who use his devices that we owe our present advantages over our forefathers. I would not belittle the achievements of the so-called practical man, but the public must be taught that application can never run ahead of the knowledge to be applied and that the only road to higher achievement in practical things is by the further development of pure science.

The *main product* of science, using that word in its broadest sense, is *knowledge*; among its by-products are the technological arts, including invention, engineering in all its branches and modern industry. Not all industries have attained the character of a technological art. Burning the woods to drive out game and thus obtain a dinner, is a form of industry. Like it in character are some very large industries, such as agriculture of the sort that impoverishes the soil; lumbering that destroys forests and incidentally ruins rivers and increases erosion; coke making by processes that waste forty per cent. of the energy of coal. The production of power from coal by means of the steam boiler and the reciprocating engine we at present regard as a

highly developed technological art; yet it is a process which at the very best converts less than ten per cent. of the total stored energy of the fuel into available form. If the ultimate purpose of this power is the production of light, we by our present methods suffer a second waste of ninety per cent. or more, so that the efficiency of the combined processes is but a fraction of one per cent. These things are excusable while ignorance lasts. They become criminal with realization of the results and are inconceivable in a community of fully developed civilization. Science paves the way for the gradual supplanting of these barbarous methods by more refined and rational processes, but they often persist long after they are known to be injurious to the public welfare because they happen to serve some selfish individual or corporate purpose. In such cases it is to science again that we must look for the development of an enlightened public opinion that will end them.

Nearly all really important technical advances have their origin in communities where the great fundamental sciences are most extensively and successfully cultivated. In the field of artificial illumination, to take a concrete example, each successive improvement over the tallow-dips and whale-oil lamps of our ancestors has come to us from over the water.

The first building to be lighted by coal-gas was the chemical laboratory at Würtzburg (1789). Illuminating oils were being made from petroleum by Binney and Young, in England (1850), at a time when we were bottling our crude oil and selling it for liniment.

During the later years of the nineteenth century occurred the sudden development of arc-lighting in this country; a change from darkness to light unprecedented and almost unimaginable. This magical transformation from conditions but little re-

moved from medieval darkness was largely due to the ingenuity of Farmer, Brush, Elihu Thomson, Weston and numerous other American inventors, backed by an energetic people keen to adopt whatever appeals to them. The electric arc, however, was discovered by Sir Humphry Davy (1806). It was the development of the voltaic battery by Grove and Bunsen (1840) that gave the first impetus to electric lighting, and of the dynamo by Gramme and Siemens that made it a commercial possibility. Arc lamps had been in regular use in the lighthouses of England and France since 1858; a factory in Paris was thus illuminated in 1873; widespread public interest in arc-lighting was first kindled by the dazzling display at the Paris exposition of 1878.

Lighting by glow-lamps, like arc-lighting, had its first great growth in America. Nine years after Edison's announcement of his plan of installing high-resistance lamps in multiple in a constant potential circuit, and his public demonstrations at Menlo Park of the practicability of the scheme, over three million such lamps were in use in the United States.² The incandescent lamp, however, with the essential feature of a carbon filament in *vacuo*, seems to have originated, although not yet in practicable form, with Swan in England some years previous to 1879.³

To Auer von Welsbach, Nernst and Bremer, in Germany, we owe the use of the oxides of the rare earths as illuminants; to Arons, of Berlin, the mercury arc in its original form; to various inventors and experimenters across the water the new filaments of tantalum, tungsten and other refractory metals that are rapidly replacing our filaments of carbon. The Pintsch gas which lights our railroad trains is likewise a German invention.

² T. C. Martin, *Electrical World*, Vol. IX., p. 50.

³ Dreidge, "Electric Illumination."

In the matter of acetylene, although priority for its commercial production was awarded to Wilson in Canada, the process historically considered is obviously traceable to the scientific researches with the electric furnace at the hands of Moissan in France. The absorption of acetylene by acetone, which makes storage in portable form of that brilliant illuminant practicable, is likewise a European idea.

This summary of facts does not display an exceptional, but a prevalent, condition. It might be duplicated in almost any department of technology. Although we in this country have had a hand in the development of the art of generating power nearly every important step in the use of steam originated in Europe, as did most of the devices pertaining to boilers and engines; such as gauges, injectors, governors, condensers and the like. This is not strange, in the case of the reciprocating engine, which is an old-fashioned machine, a relic, the continued use of which is due chiefly to the extraordinary tendency of the race to cling to the things of the past. It is true, however, to no less extent of the invention of internal combustion engines, steam turbines, water turbines and of the whole family of electrical devices for the transmission of power. Generator and motor, transformer and storage battery alike had their inception overseas. It is the same in artificial refrigeration, in telegraphy, in photography; indeed, in nearly all the arts that are based upon the fundamental science of physics. In the great fields of industrial chemistry, especially, European preeminence is universally admitted.

All this does not mean that we do not deserve our popular reputation as an ingenious people, facile and versatile, quick to grasp and put to use any novelty. Nowhere else in the world has cunningly de-

vised and admirably designed machinery been made to supplement and supplant hand labor so successfully; we have indeed a passion and a genius for invention. But it is one thing to contrive clever mechanical combinations based upon simple principles long since established and familiar in every machine shop and quite another to possess the combination of profound chemical knowledge and technical skill that have yielded such extraordinary results in the glass works at Jena, or the mathematical ability to develop the theory of lenses to the point which has made it possible to design the wonderful optical instruments that have made the same little German town famous.

Many inventions that did not originate with us have found their widest field in this country. Many foreign ideas have first obtained practical form for general purposes here. We were among the first and continue to be by far the most extensive users of the electric railway. In Davenport, Page, Farmer, Green and others we count pioneers of the pre-dynamic period worthy to be named with Davidson, Pinkus, Jacoby, Bessolo and other European inventors of their day. Nevertheless it was Pacinotti, Gramme and Siemens who gave us the electric motor; it was at Sermaize in France that the classical experiment of plowing by electricity was performed; it was at the industrial exhibition in Berlin, in 1879, that the first electric road in the modern sense was operated. The first roads for ordinary everyday public service were the Berlin-Lichterfelde Line and the Port Rush Electric Railway, in Ireland, a third-rail system supplied with water-power. Budapest had the first successful underground trolley road. The most advanced type of electric traction by the use of alternating currents, as exemplified in Switzerland, northern Italy and elsewhere has only very

recently received serious attention in this country.

We transmit a larger amount of energy over greater distances and at higher voltages than any other people, but the practical possibility of such transmission was first exemplified by the sending of power from the waterfalls at Laufen 100 kilometers away, to the electrical exhibition at Frankfort-on-Main, in 1892.

It is not a question of American *versus* European skill, but of the conditions under which useful applications are likely to originate. The history of technology shows the essential condition to be scientific productiveness.

A country that has many investigators will have many inventors also. A scientific atmosphere dense enough to permeate the masses brings proper suggestions to many practically inclined minds. Where science is there will its by-product, technology, be also. Communities having the most thorough fundamental knowledge of pure science will show the greatest output of really practical inventions. Peoples who get their knowledge at second-hand must be content to follow. Where sound scientific conceptions are the common property of a nation the wasteful efforts of the half-informed will be least prevalent. The search after perpetual motion, the attempt to evade the second law of thermodynamics and the promotion of the impracticable are all simply symptoms of a people's ignorance.

Modern invention is a very near neighbor to the pure science of the laboratory and the relation becomes daily more intimate. Nothing could apparently be more academic in its early development or further from the practical workaday world than the subject of electric waves. For years it was regarded as a fine field for the speculations of the mathematical physicist. Then at the hands of Hertz and his

followers it became a fascinating topic for experimental investigation by men devoted to science for its own sake. Suddenly it was launched into the realm of hard-headed commercialism by a practical man, daring, enthusiastic and optimistic enough, at a time when electric waves could be produced in one room of the laboratory and detected in the next room, to dream of sending such waves across the sea as bearers of human messages.

At every step of its development the things that have made wireless telegraphy possible have been borrowed from pure science.

While Marconi was still struggling to adapt the apparatus of Righi to long-distance transmission the antenna and the coherer were already in use by Popoff⁴ in the study of oscillatory lightning. In the thermal detector of Fessenden the almost invisible platinum wires produced years before by Wollaston for the cross-hairs of telescopes appear in a new field of usefulness. The "lead-tree" familiar as a simple and beautiful lecture experiment in electrolysis forms the basis of the responder of DeForest. Another form of electrolytic detector introduced independently as the receiver of wireless signals by Schloemilch and by Vreeland traces back to the Wehnelt interrupter. Marconi's latest receiver, the magnetic detector, is an ingenious modification of Rutherford's device for the study of electric waves and this in turn was based on the classical experiment of Joseph Henry on the effects of the discharge of Leyden jars on the magnetization of steel sewing needles.

It is needless to multiply examples. In the history of science and of invention this intimate relation appears to be almost universal.

In this country science is making a great

⁴ Popoff, *Journal of the Russian Physical Chemical Society*, Vols. 28 and 29, 1895.

growth, particularly in material equipment. The number and size of our special societies is increasing year by year. The American Association for the Advancement of Science has already a membership of more than 6,000. Our scientific journals are steadily growing in influence and importance. Colleges everywhere are building laboratories and the universities are increasing their facilities for research. The federal and state governments are beginning to recognize the necessity for scientific investigation and to foster it.

Nevertheless there is much to be done to bring us up to the European standard. Our position is like that which exists in agriculture. The total product of wheat and corn is enormous, but when we consider bushels per acre we realize the superiority of the intensive cultivation of older countries. In science likewise our total output is creditable, but our specific productiveness is still low. The discrepancy can hardly be ascribed to inferiority of intellect or to lack of industry, for we are of the same stock as those who have created modern science and who have given it its high place in other countries. For an explanation we must look, rather, to environment and to the conditions under which scientific work is done here and abroad.

Now the environment of science has always been academic. Science has its home in the university. From Galileo and Newton to our own time the men who have laid the foundations upon which civilization is built have nearly all been teachers and professors.

A few notable exceptions there are, such as Darwin, whose centenary we are about to celebrate. Each branch has its short list of unattached investigators—Franklin, Rumford, Carnot, Joule in physics, etc., but the honor-roll of science is essentially an academic list.

It is so in America as elsewhere, but abroad the dictum of the university is authoritative; with us the term *academic* is one of contempt. European practise is confidently based on theory, but in America men of affairs habitually use the word *theoretical* as synonymous with impracticable, unworkable and not in accordance with fact.

It is necessary, therefore, in considering the place of America in science, to contrast the standing of our educational institutions, not pedagogically, but as centers of research, with those of our neighbors. I attempt no general comparison but offer only a single simple illustration drawn from the one branch of science for which I feel competent to speak: Holland has but four universities, with less than four thousand students in all. There are in this country at least fifty institutions larger and better equipped on the average than the Dutch universities. If we were on a par with Holland in physics, for example, we should have seventy or more university teachers, who were, at the same time, investigators of the rank of Lorentz, Zeeman, Julius, Ohnes, Haga and Van der Waals. I shall not venture into other sciences, but leave my colleagues to make their own comparisons.

We have less than our share of men of science because we have not, as yet, universities that sufficiently foster and encourage research. When in any of our institutions a man distinguishes himself by productive work he is frequently made a dean, director or even president, and is thus retired from what might have been a great career as an investigator. Thereafter he is compelled to devote himself to administrative duties, which some one not equipped for the important task of adding to the world's stock of knowledge might just as well perform. It is as though the authorities were to say: *X* has written an

admirable book; we must appoint him bookkeeper—or *Y* is developing a decided genius for landscape; we will increase his salary and ask him to devote all his time to painting the woodwork of the university buildings. Nor does the mischief stop with the sacrifice of a few bright spirits. It extends to the bottom. The head of each department is a petty dean, cumbered with administrative detail. He is expected to hold every one under him to account, not for scholarly productiveness, but for the things which chiefly hinder it.

In this exaltation of administrative ability over creative gifts which are much rarer and more precious, our institutions share the weakness which pervades our industrial establishments where the manager or superintendent usually gets larger pay and is regarded as more important than the most expert craftsman. In both we see the same striving for a certain sort of efficiency and economy of operation and for the attainment of a completely standardized product. This tends in both cases to the elimination of individuality and to sterility. In the university it retards instead of developing research. In industry it discourages originality. I would that there might be displayed in the administrative offices of every institution of higher education this testy remark once made by an eminent scholar: "*You can not run a university as you would a saw-mill!*"

If any one questions the responsibility of the American university for the shortcomings of American science and is inclined to seek some more obscure cause for the conditions that I have endeavored to portray, let him consider the history of astronomy in this country. This science for some reason was from the first accorded favors not vouchsafed to any other branch of learning. Colleges that made no pretence of research and had neither laboratories nor libraries worthy of the name were

ambitious to have observatories, and rich men were found to establish and endow them. The observatory implied, somehow, to the minds of the authorities, an astronomer—not merely some one of good moral character who could teach the subject—and so it came about that there was one member of the college faculty who was expected to do scientific work and was left comparatively free to observe and investigate. Modest as most of these early provisions for astronomy were, they bore fruit, and American astronomy gained standing and recognition while her sister sciences were struggling for existence. Later, it is true, there arose an ambition for laboratories and there were laboratories; but unfortunately, save in very rare instances, the laboratory has not implied an investigator. The conditions which made astronomy what it was have not been repeated. Productiveness has not been demanded nor expected; neither have the inmates of our laboratories been accorded that exemption from excessive pedagogical duties which would enable them to give their best strength to research. Were it otherwise I should not now be reminding you sadly of these deplorable *home-conditions* of our sciences, but singing their achievements.

A recent event in the educational world well illustrates the weakness of our academic attitude toward science. The head of one of our strongest, most modern, most progressive and best equipped institutions has announced, as one of the details of a noble bequest to the university, the endowment of ten research professorships.*

President Van Hise declares:

The provisions for their support, including liberal salaries, assistants, materials, a limited amount of instructional work, and relations with students, are an epitome of the situation in the

best German universities, which are admitted to stand first among the institutions of the world in the advancement of knowledge.

This is indeed an event to warm the heart of every one who is interested in the promotion of science. All who are devoted to learning for its own sake or who realize the importance of science to the welfare of the nation will applaud that portion of the will in which this great gift is made, which reads:

The university may best be raised to the highest excellence as a seat of learning and education by abundant support in pushing the confines of knowledge.

And yet in very truth there is nothing to prevent the University of Wisconsin, or any other of a hundred of our institutions, without awaiting the rare advent of some far-sighted benefactor, from having, not ten, but all her professorships made research professorships—nothing, alas, but the deep-seated and seemingly uneradicable conviction of our boards of control, that the endowments committed to their charge are for some other purpose.

A true university from the standpoint of scientific productiveness is a body of scholars; that is to say, of men devoting themselves solely to the advancement of learning. Every one in it from top to bottom should be an investigator. The entire income of a university should be expended in the promotion of science, i. e., of knowledge. Teaching is a necessary factor in the advancement of learning and so a function of the university. University teaching should be done by investigators not only because more investigators are to be developed, but because the promotion of science, on the scale which the future demands, means that science shall not remain narrowly academic, but shall more and more pervade the life of the people.

From the standpoint of American institutions such a definition of the university

* "Memorial Exercises in Honor of William F. Vilas," SCIENCE, XXVIII., October 30, 1903, p. 601.

is revolutionary, but it can not be said to be impracticable or Utopian; for upon precisely such ideals the most successful university systems in the world have been built.

That this type will bear transplanting to American soil was triumphantly demonstrated in the work of Daniel C. Gilman, who gave the Johns Hopkins University at its inception the essential characteristics of the German universities as regards research. This successful experiment should have marked an epoch in the history of higher education, but a generation has passed and we have not as yet a university system devoted primarily to the advancement of learning. We still consider investigation merely as a desirable adjunct to university activities: never as the thing for which the university exists.

Germany, on the other hand, has for a century consistently developed the university as a center of research and through the promotion of pure science in the university has made German civilization what it is to-day.

I would not be understood as urging German or other European methods in all details upon a country where quite different conditions exist but one general principle is of universal application. In whatever we have to do, whether it be municipal administration, sanitation, road-making, the construction of water-ways, the development of industries, or the conservation of natural resources, the fullest and latest scientific knowledge should be utilized. Practise should not be permitted to lag indefinitely behind theory and that they may go hand in hand public work and private enterprises should be in the hands of *those who know*. At the same time science should be persistently advanced by every possible agency:

As American men of science we should demand for America also universities

whose purpose is the production of knowledge. There are those who will reply to such a demand that we need not look abroad; that we are already developing an educational system better for our purposes than any that has hitherto existed. So be it, but whatever pedagogical experiments we may choose to try, science and the advancement of learning must not be forever sacrificed to them. *We need not merely research in the universities but universities for research.*

To my mind the future of science in America as elsewhere is essentially a question of the future of the universities. It is conceivable that our institutions may so long continue blind to their chief function as to be supplanted by some new agency called into existence to take up their neglected work. Already great endowments for the promotion of research quite without any pedagogical feature, have come into existence. For all such science has need and will have increasing need as our situation becomes more acute and we are brought closer to the great crisis.

But it will be found that the conditions for maximum scientific productiveness are precisely those which would exist in the ideal university. All attempts at a machine-made science are doomed to failure. Science-making syndicates are likely to meet ship-wreck on the very rocks on which our American educational system is already aground. No autocratic organization is favorable to the development of the scientific spirit. No institution after the commercial models of to-day is likely to be generously fertile. You can contract for a bridge, according to specifications. If a railway is to be built and operated a highly organized staff with superintendents and foremen and an elaborate system reaching every detail may be made to yield the desired results. No one, however, can draw up specifications for a scientific dis-

covery. No one can contract to deliver it on a specified day for a specified price. No employee can be hired to produce it in return for wages received.

To the investigator the considerations I have endeavored to present are unimportant. Science for its own sake is his sufficient incentive; but it is all important for the community at large to realize that no real addition to knowledge is useless or trivial; that progress depends on scientific productiveness; that science, which must be fostered if we are to continue to prosper, is a republic whose watchwords are *liberty, equality, fraternity*.

World power in the near future is to be a question of knowledge—not of battleships—and what is now spent on armaments is to be devoted to its pursuit.

Beyond lies that future in which it will no longer be a question of supremacy among nations but of whether the race is to maintain its foothold on the earth. For that great struggle we shall need knowledge, and ever more knowledge, and it is high time that we should prepare for war in these days of peace and plenty.

EDWARD L. NICHOLS

CORNELL UNIVERSITY,
December 14, 1908

UNIVERSITY REGISTRATION STATISTICS II.

Taking up the registration at the universities in order, we find that the *University of California* shows an increase of 75 in the graduate school, of 96 in the undergraduate body in arts, science and engineering, and of 77 in the professional schools. In arts there are 79 more men and 43 fewer women, a net gain of 36. The enrollment in the summer session exhibits an increase of 228 over 1907. The 95 students registered in law are enrolled in the Hastings College of the Law in San Francisco. Besides these there are 24

seniors and 17 graduate students in jurisprudence at Berkeley, of whom a considerable number are candidates for the degree of *juris doctor*, these 41 students thus in reality constituting a graduate school of law. Of the extension students about 750 are enrolled in San Francisco, about 150 in Stockton, and about 250 in Sonoma, and there are other centers in process of organization. Mr. James Sutton, recorder of the faculties, reports as follows:

Professor Eugene W. Hilgard, who was called to the University of California as professor of agriculture in 1874, has retired from the active work of the department, and Professor Edward J. Wickson becomes professor of agriculture and director of the agricultural experiment stations. Professor Frank Soule, who became a member of the faculty in 1869, has been appointed professor of civil engineering, emeritus, and has been succeeded as the head of the department of civil engineering by Professor Charles Derleth, Jr., formerly associate professor of structural engineering. The regents have established a professorship of psychology, and have appointed thereto Professor George M. Stratton, who since 1904 has been professor of experimental psychology at Johns Hopkins. Another chair established during the year was that of professor of agricultural practice and superintendent of farm schools. The first appointee is Leroy Anderson, formerly of Cornell University. To the chair of Romance languages, which has been vacant for several years, the regents have appointed Professor William Albert Nitze, until recently professor of Romance languages in Amherst College. The department of Semitic languages suffered grievous loss in the death, on April 27, 1908, of its founder and head, Dr. Jacob Voorsanger. Assistant Professor William Popper is in charge of the work of the department.

Plans have been prepared for the Boalt Memorial Hall of Law. Mrs. Boalt's original gift was \$100,000, but members of the California bar have pledged an additional \$50,000 to complete the building. In addition, there is available a considerable fund for a law library. Construction work upon the new Doe Library is well advanced. Present plans contemplate the completion immediately of the northern part of the building, which will amply allow for library needs for several years to come. The amount available at the

present time for construction is \$575,000. The building now under way will contain a main reading-room with accommodations for 400 readers and several smaller reading-rooms. There will be 29 seminar-rooms, 2 class-rooms, besides the usual administrative departments of a large library. The book stacks will have a capacity of 300,000 volumes and will be capable of extension indefinitely. As an annex to the agricultural building, there has recently been erected the so-called fertilizer control laboratory. The work of this laboratory is of immense importance to agriculture and horticulture in California. A building for the departments of hygiene and pathology is under construction near the Rudolph Spreckels physiological laboratory. The frame building which houses the department of architecture has been enlarged this year to three times its former capacity. On the university farm, at Davis, there have been erected a creamery, a live stock judging pavilion, and several cottages for the members of the staff. In addition, contracts have been let for a dairy barn and sewer system. The university has begun the erection of a galvanized iron temporary building as a museum of vertebrate zoology. The collection of representative specimens of Californian vertebrate fauna will be immediately begun under the direction of Mr. Joseph Grinnell. Miss Annie M. Alexander, of Oakland, has agreed to give to the university the sum of \$7,000 yearly for seven years to equip and maintain the museum.

The Massachusetts Association for the relief of California, organized shortly after the great earthquake and fire of 1906, has remitted to the San Francisco Relief and Red Cross funds (incorporated) the sum of \$100,000, being the balance of the relief funds in the hands of the Massachusetts Association upon the completion of the active work of relief. In accordance with the recommendation of the Massachusetts Association, this money has been paid over to the regents of the University of California for the university hospital in San Francisco, provided that the hospital shall always maintain at least ten free beds to be known as the Massachusetts beds and a ward to be known as the Massachusetts ward. In the assignment of these beds the university is to give preference to deserving sufferers of the disaster of April 18, 1906.

Last year we reported the installation of the Bancroft library of American history and the transfer of this collection to the library of the newly organized Academy of Pacific Coast History, in one of the university buildings at Berkeley.

Very soon after the Bancroft collection was brought to the university, the "lost Carondelet papers" were discovered among the miscellaneous manuscripts of the collection. Baron de Carondelet was the last Spanish governor of Louisiana, and historians have long known that his papers must be in existence somewhere. An eminent historian has declared that the discovery of these papers will necessitate the rewriting of the history of the southwest.

Perhaps the most unusual gift ever made to the university was that received by President Wheeler on Friday, September 25. On that evening a stranger called at Dr. Wheeler's house, saying that he was a messenger from a man "up in the woods" who wished to "grubstake" some student who was working his way and needed a little money to help him finish his college course. The stranger then delivered a small sack containing \$349 in coin. The amount had been \$350, but one dollar had been allowed the messenger for delivering the money. No clew to the identity of the donor could be obtained. The gift will be known as the Grubstake Loan Fund.

The *University of Chicago* shows a gain of 242 in the fall and of 414 in the summer enrollment, or one of 520 in the grand total for the year, 540 summer students having returned for work this fall, as against only 404 last year. The greatest gain in the fall registration, one of 167, is found under "other courses," which embrace those given for teachers afternoons, evenings and Saturdays. There is a loss of 15 men in the college, which is offset by a gain of 17 women. The professional and graduate schools all exhibit a small increase.

The enrollment of *Columbia University* shows a highly gratifying increase in all departments. The total registration represents a gain of almost 500 students over last year, of which over 80 per cent. can be credited to the fall registration. The grand total this fall exceeds that of two years ago by over 1,000 students, a growth of 22 per cent. in that brief interval. Both *Columbia* and *Barnard* colleges (arts, men and women, respectively) show a sub-

stantial increase over last year's figures, the entering class being the largest in the history of each institution. The non-professional graduate schools of political science, philosophy and pure science, taken as a whole, continue to share in the general growth of the university, although the faculty of philosophy has experienced a slight loss, no doubt owing to the establishment this fall of free courses for teachers by the College of the City of New York. The total enrollment of graduate students, including those with their major subject in education—primarily registered at Teachers College—is 958, as against 938 in 1907 and 513 in 1902. The professional schools, without exception, have made encouraging gains in attendance, the schools of mines, engineering and chemistry having recorded the largest increase in actual number of students, namely, one of 92, whereas the largest percentage gain has been registered by the school of law, namely, one of almost 30 per cent.; the entering class in the medical school shows a growth of no less than 40 per cent., while pharmacy has gained 55 students. Including students from the college registered in the professional schools, the total enrollment of these schools is as follows: Law, 346; medicine, 318, and mines, engineering and chemistry, 699. The almost phenomenal development of Teachers College continues without interruption, there being 950 students enrolled this year, as against 563 in 1902. The two residence halls for men are practically filled this year, and the erection of a third dormitory for men has become a need sooner than even the most optimistic anticipated. The summer session was even larger than that of the preceding year, the total attendance being 1,582, as against 643 in 1902, 84 of the students being registered at the medical school in 1908. The 655 officers are ex-

clusive of 87 instructors in the Horace Mann and Speyer Schools, as well as of the summer session staff. In 1906 there were 571 officers. The extension work continues to make satisfactory progress, the evening technical courses established the winter before last attracting many students.

The domestic economy building in process of erection at Teachers College should be ready for occupancy before the close of the year, whereas work has been temporarily discontinued on Kent Hall, the new building for the schools of law and political science.

The incumbent of the Kaiser Wilhelm professorship this year is Professor Albrecht Penck, of the University of Berlin, whose subject is physiography, Professor Felix Adler, of the Columbia department of philosophy, being the third incumbent of the Theodore Roosevelt professorship at the University of Berlin. President Benjamin Ide Wheeler, of the University of California, has been selected by the trustees as the Theodore Roosevelt professor for 1909-10.

The sum total of the gifts received in money during the year is \$329,385.39, while the grand total of such gifts received in the last seven years is \$10,286,296.58. The total outstanding debt of the university is \$3,429,156.45; the income for 1907-8 amounted to \$1,960,258.40, and the annual budget for 1908-9 provides for the expenditure of almost two million dollars.

An amendment to the statutes was adopted by the trustees on February 3, 1908, which provides that "each professor and adjunct professor shall be entitled, once in every seven years, to a leave of absence of one year on half pay, or to a leave of absence of one half year on full pay, such period of absence to count as service to the university." This provision renders it possible for those officers who

can not live for a year upon half of their present salaries to secure eight months' absence once in seven years on full salary. During the year the statutes were also amended in order to establish the new grade of associate, ranking below the grade of adjunct professor and above that of instructor. It is to be employed "in the case of an officer of instruction who is not expected to devote the greater part of his time to the service of the university, but to give statedly a limited amount of instruction upon a special subject."

A system of academic advisers was put in operation in Columbia College last spring, "by the terms of which each undergraduate student is assigned to the oversight and care of an officer of instruction, who becomes his guide and friend as well as his teacher. By frequent personal meetings and conferences, it is the duty of the adviser to keep himself closely informed of the progress and academic life of each of the small group of students assigned to him and to give to such students the counsel and direction which they need, not only in regard to their studies but in regard to all phases of their undergraduate activity and life."

The requirements for admission to the medical school were recently revised, "so that, from and after July 1, 1910, the minimum requirement will be the completion of not less than two full years of study in an approved college or scientific school, which course must have included instruction in the elements of physics, in organic chemistry and in biology."

Cornell University reports a gain of 407 in the grand total, to which the fall enrollment has contributed 368, the summer session showing an increase of 86 in actual number of students. All of the faculties have experienced an increase this fall with the exception of medicine, where increased

standards for admission have resulted in a reduction of the attendance by 109. The academic registration and the engineering enrollment both show a gain of 94 students, agriculture one of 69, architecture of 30, law of 23, the graduate school of 41. The students listed under "other courses" are taking the short winter course in agriculture, and there are 114 more of these than there were last year. Of the 1,727 engineering students, 1,158 are registered under mechanical and 569 under civil engineering.

Harvard University's grand total is to all intents and purposes equal to that of last year, but there has been a loss of 37 in the total fall enrollment. The loss of 37 men in the college is offset by a gain of 34 women in Radcliffe, the scientific school suffered a decrease for the reason explained in full last year, the law school has lost 26 students, the graduate school of arts and sciences has gained 18, while medicine, dentistry and divinity have remained practically stationary. The summer session of 1908 was larger by 224 students than that of the previous year, and there has been a gain of 61 in the number of instructors. Of the extension students, 1,119 are registered in courses offered at the Lowell Institute by Harvard instructors, and in the case of qualified candidates, counting towards a Harvard degree.

The new graduate school of business administration attracted 56 students; it furnishes a two-years' course leading to the degree of master in business administration. The Bussey Institution has ceased to exist as an undergraduate department for instruction in practical agriculture, the Bussey fund being now devoted to advanced instruction in problems relating to agriculture, such as economic entomology, animal heredity, experimental plant morphology and comparative pathology of animals.

The *University of Illinois* shows consistent gains in every department, with the exception of music, where there has been a loss of 24 students, of library science ("other courses"), which reports a loss of 10 students, of art, where the registration has been reduced from 10 to 4, and of law, where the registration shows a falling off of 3 students. The largest gain, one of 68, is in the graduate school, while medicine has gained 48, and the male academic and commerce each 37. Architecture, pharmacy and dentistry have also gained over 30 students each. The total increase in the fall enrollment amounts to 247 students, while the summer session was larger by 101 students than that of 1907. Owing to the fact that the percentage of summer-session students who returned for work in the fall was considerably greater in 1908 than in the year preceding, the gain in the grand total over last year is only 228. The total registration in 1903 was 3,239, as against 4,400 this year, a gain of 35 per cent. in five years.

The distribution of students by faculties under *Indiana University* is somewhat different from what it was last year, and it is consequently difficult to make accurate comparisons. The loss in law and the gain in medicine have been explained above. There are 9 more women in the academic department than there were last year, while a loss of 66 students in the graduate school is more than offset by a gain of 122 men in the college, but this may be due to the inclusion this year of a number of graduate students in the academic department. The total increase in the fall enrollment is 192, and the summer session exhibits a gain of 284, the growth in the grand total being one of 446.

The *State University of Iowa* exhibits an increase in every department except that of dentistry, which reports a loss of 16

students, and those of medicine and music, where the enrollment has remained stationary. The largest gain is in the academic department, namely, one of 85 men and 60 women, whereas the scientific schools have only two more students than last year. Pharmacy has gained 14, law 10, the graduate school 11, and the nurses' training schools (other courses) 9, the increase in the entire fall registration being one of 158 and in the grand total for the year one of 168, the summer session of 1908 having been slightly larger than that of the preceding year. In the fall of 1903 there were only 1,260 students registered at Iowa, as against 2,356 this year.

The standards of admission to the law school were raised this fall, inasmuch as no students were permitted to enter who did not present the entire thirty credits or fifteen units, whereas in previous years students were admitted with deficiencies aggregating three credits. Beginning with September, 1909, one full year of college work, in addition to the four years of high school work formerly required, will be demanded for admission to the school of medicine, and beginning with September, 1910, the requirement will be still further increased to two years of college work. Beginning with September, 1909, the requirements for admission to the college of dentistry will be advanced to four years of high-school work. No other changes in the standards of admission to the several schools of the university are in immediate contemplation.

The university has completed during the past year an extension to the engineering building at a cost of about \$75,000. The extension duplicates the capacity of the building, and completes the first wing of the engineering quadrangle. A building for the law school is now being erected. This building will cost \$125,000, and will be completed in about a year. Both of the buildings mentioned are of Bedford stone, fireproof construction, in accordance with the general plan of the

regents, and in their location the regents have followed the plan of the ultimate campus, which has been prepared by landscape architects.

Johns Hopkins University has gained 47 students since last year, of whom 30 are found in medicine and 17 in the graduate school, the academic department having remained stationary. In 1902 there were 162 students in the college (166 in 1908), 329 in medicine (1908: 355) and 179 in the graduate school (1908: 177).

The scientific schools (— 10), medicine (— 9) and art (— 3) have suffered slight losses at the *University of Kansas*, which are much more than offset by gains in the other departments, the academic department alone contributing an increase of 106 students—77 women and 29 men. Law has gained 22, music 19, pharmacy 8 and the graduate school 12, the total increase in the fall registration being 108. The summer session enrolled 89 students more than that of 1907, the increase in the grand total being one of 154 students.

The *University of Michigan* reports an increase in the fall registration of 148 students, law alone exhibiting a loss (41 students), while medicine has remained uniform. The academic department has registered a net gain of 45, this figure representing an increase of 47 men and a decrease of two women. The graduate school has gained 65 students, the scientific schools 28, dentistry 23 and pharmacy 7. The summer session was slightly larger than that of the preceding year, but the number of those enrolled both in the summer term and the regular college year was considerably smaller, resulting in an increase in the grand total of 235 students. The attendance at Michigan passed the five-thousand mark for the first time this year, it having reached 4,000 in 1904. Mr. Shirley W. Smith, secretary of the university, has submitted the following items of general interest:

The session of the summer of 1908 for the academic department was for the first time in our experience fixed at eight weeks instead of six, and the fee was raised from \$15 to \$20. The fact that this change was followed by an increase in attendance of thirteen per cent., which increase was largely made up of those not enrolled in the regular session, is interesting as showing the demand by teachers for the largest opportunity for actual summer work.

Our engineering faculty have made provision for a six-year course, by the completion of which students will secure a broader foundation of general culture and larger technical attainments. We shall look forward with interest to see whether these increased opportunities will meet a real demand in the education of young men preparing for the active life of to-day.

In our law department we have sought to encourage and to recognize the superior equipment of those who combine academic with legal training, and have established the degree of J.D. (*juris doctor*) to be conferred upon certain college graduates completing the full three years' law course. The age of admission to the first year class of the law department has been raised from eighteen to nineteen years, with a corresponding higher age requirement for the two upper classes.

In the material equipment, our most important additions are as follows: An extensive addition has been made to the observatory building, including a new dome 40 feet in diameter. We are installing a large reflecting telescope which is now approaching completion. This instrument has been designed especially for photographic and spectroscopic work, and it is arranged for use either as a Newtonian or as a Cassegrain reflector. When used in the latter manner, the mirrors give a three-fold magnification with an equivalent focal length of 60 feet.—We have acquired by gift of an alumnus and from the city of Ann Arbor a tract of land of about ninety acres to serve as a botanical garden and arboretum. This land has an exceptional variety of soil, elevation and exposure, including a border of over one half mile on the Huron River, and the tract is easily accessible from the campus. The opportunities for the study of landscape gardening by our students in engineering, architecture, forestry, and general culture, as well as those in botany and landscape gardening proper, are considerably extended by this gift.—The Woman's League of the university has purchased a seven-acre tract of land, very convenient of access, which will be developed as an

athletic field for the women of the university.—Another welcome gift is in the form of about fifteen hundred acres of land, the purchase price of which, beyond possibly ten per cent. of the value, was donated to the university, lying along the shores of Douglas Lake in Cheboygan County. This land will serve as the site for our summer engineering camp, and its topography, including forest and open, land and water, various elevations, etc., is particularly well adapted to the purpose, and we also look forward to its use as a biological station of importance. In honor of the donor it has been named The Bogardus Engineering Camp.—Buildings completed or practically so during the year include the memorial hall, the gift of alumni and other friends, and a new building for the dental college. The latter, erected at a cost of \$125,000, is probably responsible in a large part for the increase in our enrollment in the dental college. Contracts have been awarded for a chemical laboratory to cost \$245,000 and an addition to our engineering building to cost \$75,000.

The *University of Minnesota* shows a slight decrease in pharmacy, but has made good gains in all other departments, especially in the schools of agriculture (102), law (99) and medicine (69). The increase in the law school is due to the fact that this is the last year in which students may enter that college upon presentation of a high-school diploma. Beginning with September, 1909, all students entering the college of law will be required to have one year of regular academic work in the college of science, literature and the arts. The large growth in medicine is due to the fact that the medical department of Hamline University has recently been absorbed by the University of Minnesota, which now conducts the only medical school in the state. The college of engineering entered this fall upon the five-year course leading to the degree of B.S. at the end of the fourth, and the professional degree at the completion of the fifth year. The school of mines shows no falling off in enrollment, although the entrance requirements in mathematics were raised this fall. The agricultural

department has developed rapidly as a result of the impetus given to that line of work throughout the state, larger provision being made for agricultural training than ever before. The academic department shows a net gain of 42 students, namely, a gain of 48 men and a loss of 6 women, the number of women, however, being still far in excess of that of the men. Compared with last fall, there has been an increase in the total of 398 students, and a practically similar gain if the summer session be included.

Mr. Irvin Switzler, registrar of the *University of Missouri*, reports as follows:

The total registration of the present session shows a relative as well as an absolute increase when compared with preceding sessions. The rate of increase during the two preceding sessions was a trifle less than ten per cent. The registration of the present session exceeds that of the corresponding date of 1907 by 284 students, an increase of almost exactly twelve and a half per cent. This increase is found chiefly in the college of arts and science, the teachers college, the school of agriculture, the department of law and in the department of journalism, which was inaugurated this session with an enrollment of 60, as indicated in the table under the head of "other courses."—The steady increase which has been noticed in the college of arts and science in preceding sessions has continued, being due to the growing appreciation on the part of students of the advantages of college preparation for professional work. The rapid growth of the high schools in Missouri has led to an increased demand for trained teachers. This has contributed to the increase in the teachers college, which has also attracted many superintendents and principals who desire advanced courses.—While the engineering courses show a slight increase, the freshman classes in this department show a decrease, probably due to the effect of the financial depression upon the demand for graduates in engineering. Some who would otherwise have entered the engineering department have taken up agriculture. The registration in this school has also been favorably influenced by the spread of information regarding the importance of scientific training in this field.—The department of law has recovered the ground lost during the preceding session, on account of

increased entrance requirements, and has in addition made a substantial increase. The department of medicine has suffered from the uncertainty regarding the future due to plans for removing the last two years to St. Louis or Kansas City. The matter is still pending, but will be determined during the present session. While the graduate department shows exactly the same registration as during the preceding session, the number who are candidates for degrees has increased.

On account of ill health Dr. R. H. Jesse resigned as president of the university on July 1, after an administration of seventeen years, and was succeeded by Dr. A. Ross Hill, formerly dean of the college of arts and sciences of Cornell University. Before accepting the latter position Dr. Hill was dean of the teachers college of this university, and he is familiar with the educational problems of this state and section. His formal inauguration as president occurred on December 10 and 11, 1908.

This university conducts extension courses at St. Louis, Kansas City, St. Joseph, Joplin, Nevada and Sedalia, but as the registration does not begin until after November, it has not been included in the table. The registration in extension courses during the session of 1907-8 was 134.

The total gain in the fall enrollment is 265, and the summer session shows an increase of 56 students. As the first item of double registration (416) is 102 in excess of that of last year, no accurate comparisons can be made by faculties with 1907.

The *University of Nebraska* has made a gain of 342 in the grand total and of 270 in the fall total, this year's summer session having attracted 104 students more than that of 1907. Agriculture shows the greatest increase—one of 140 students, and music has gained 50. A teachers college was established this year and has drawn students from the academic department, thus at least partially explaining the falling off of 149 women in the latter department. The registration of men in the college and the law school enrollment have remained stationary, while the scientific school has lost 40, and the medical school 20 students.

The graduate school and the school of art have also suffered a slight loss.

The school of commerce has contributed most heavily (200) to the gain in the fall attendance at *New York University* of 224 over last year. Owing primarily to increased standards for entrance to the professional schools of law and medicine, the enrollment in these schools has suffered a loss—of 36 in law and of 67 in medicine. The teachers college has gained 49, the engineering school 31 students, and the academic department 19 men and 31 women, while the graduate school has remained stationary, and veterinary medicine has lost 11 students. Of the 298 men registered in the college of arts, 143 are at University Heights and 155 at Washington Square, while all of the 167 women in this division are at Washington Square. The summer session was larger by 86 students than that of the preceding year, the grand total increase being one of 303 students.

Northwestern University's grand total is about 400 in excess of last year's, representing a gain of 15 per cent. Of the 270 students mentioned under other courses, 234 are enrolled in the school of oratory and 36 are attending the special pre-medical course. Mr. William H. Long, secretary to the president, writes as follows:

Northwestern University shows an increase of almost twenty per cent. in the fall enrollment. The gain is especially noticeable in the college of liberal arts, which enrolls 480 men against 389 the year previous. On the other hand, there has been a decrease in both the percentage and the actual number of women. The gain is noteworthy coming in a year in which the tuition fee is raised twenty-five per cent. A part of the increase in the number of men is due to the fact that the first class of engineering students are included in the college of liberal arts. The college of engineering will be formally inaugurated in the fall of 1909. Mr. John F. Hayford, of the United States Coast and Geodetic Survey, has been elected director. A course has been outlined that will require five years. At the end of the fourth year

the student will receive the degree of bachelor of science, and at the end of the fifth year an engineering degree. This year students are accepted in the beginning work only. In the medical school the admission requirements have been advanced one year. The effect upon attendance has been slight, as the figures are practically the same as those of last year. The only school that shows a decided decrease is the dental school, which feels, for the first time, the full effect of the recent large increase in entrance requirements. The new school of commerce meets with remarkable success. More than 200 students are in the first year of the course. The entire course will extend through three years.

On the campus at Evanston the Swift hall of engineering is nearing completion. Ground has been broken for a new gymnasium and the foundation is nearly completed. This building is the gift of Mr. James A. Fatten. It will be of white stone and brick. It will contain a club room and social rooms for men, offices for various student enterprises, a large swimming pool, locker rooms, baths, a large gymnasium room, 87 by 135, of the usual type. A rather unique feature is the "indoor field," which will provide for field sports. This field is a room, 120 feet by 215, clear from supports, and having a dirt floor surrounded by a ten-lap-mile track of dirt. This room will accommodate a full-size baseball diamond and two of the three field positions. Plans for dormitories are under way, but their erection has been held in abeyance.

Ohio State University reports an increase in the grand total registration of 356, and gains this fall in every department with the exception of law. The college has gained 54 men and 27 women; the scientific schools 72, agriculture 45, veterinary medicine 29, the graduate school and domestic science (other courses) 25 each, pharmacy 19, forestry 18 and pedagogy 12 students, while law has lost 11. Of the 925 students in the scientific schools, 43 are enrolled in the so-called short course, two years in length, and similarly there are 68 short-course students in agriculture out of 216 and 4 in domestic science out of 119. The summer session experienced an increase of 78 students.

Mr. Edward Robins, assistant secretary of the *University of Pennsylvania*, has furnished the following descriptive material to accompany the figures of this institution:

The final figures of registration for the current academic year at the University of Pennsylvania show a substantial and gratifying increase over corresponding figures for the preceding year. The net registration for the entire university is 4,555, an increase of 277, or 6½ per cent. over last year. Every department but one has practically equaled or exceeded its registration for the previous year, and in that department additional entrance requirements, which operate for the first time this year, have materially affected the total. The college, with an increase of 127 students, now numbers 1,853. The law department has increased from 303 to 326; the department of veterinary medicine from 131 to 150; the graduate school from 336 to 339; the evening school to 272 from 223. The dental department's total, 383, is 7 less than last year's figure. The attendance in the college courses for teachers is 352, and may be increased by late registrations during the next few weeks. The summer session of 1908, with an enrollment of 472, exceeded that of 1907 by 110 students. The medical department begins the year with 563 students, or 42 less than last year, due largely, as stated above, to a raising of the standard of entrance requirements. Heretofore, the requirements for admission to this department have been equivalent to those prescribed for admission to the freshman class of the college, but for the academic year 1908-9 a knowledge of physics, chemistry and general biology or general zoology and two foreign languages is demanded. Entrance requirements for the next two years will be further raised so that in 1910-11 candidates must have completed work equivalent to that prescribed for the freshman and sophomore classes in colleges recognized by the university.

The enrollment of students in the college is distributed by courses as follows, every course sharing in the increased registration of the department: architecture, 168; arts, 323; biology, 49; chemistry, 78; chemical engineering, 58; Wharton school of finance and commerce, 463; civil engineering, 292; mechanical engineering, 387; music, 35; total, 1,853.

Interest in registration figures naturally centers in the freshman class, which this year for the whole university numbers 1,258, an increase of 126, or 11 per cent. The college shows an excep-

tional gain of 25 per cent., the enrollment now being 611. The law and veterinary medicine classes, 146 and 63, respectively, have each increased ten. The medical and dental departments each show a slight falling off, the registration being 160 and 121, respectively, as against 189 and 139 for last year. The evening school enrolls 157 regular students, an increase of 29.

The growth of the university as represented by the foregoing figures is more readily appreciated when a comparison is made with the registration of five years ago. Since 1903 the university has increased its student population 69 per cent. The college, the department of veterinary medicine and courses for teachers have practically doubled their enrollment. The graduate school has increased 68 per cent. and the professional schools have increased materially. The evening school of accounts and finance and the summer school have sprung into being during this period. The corps of professors, instructors and assistants has been augmented nearly fifty per cent., the total teaching force now approximating five hundred. The physical equipment of the university has had valuable additions in the several years past in the new laboratories and buildings of the departments of medicine, veterinary medicine, engineering and physical education, while the construction of new dormitories enables the university to house seven hundred of its students in these comfortable apartments.

Princeton University's total is practically the same as that of last year, 1,314 in 1908 as against 1,311 in 1907. The academic department lost 24 students and the graduate school 21, whereas the scientific school shows a gain of 50 students.

At *Stanford University* there has been a net loss in the fall registration of 51 students, the gain of 33 graduate students, 48 law students and 19 women in the academic department not quite offsetting the loss of 151 men in the latter department (including the scientific school). Mr. O. L. Elliott, registrar of the university, writes as follows:

A tuition fee of twenty-five dollars per semester has been instituted in the department of law, applicable to all students in law not registered in the department on March 9, 1907. (There are

no tuition fees in other departments of the university.)

The Cooper medical college of San Francisco has been transferred to the university as a free gift, and a department of medicine has been instituted in the university. Instruction will begin in September, 1909. There will be a four-years' course in medicine, preceded by not less than three years of collegiate work. One and a half years of the medical course will be given at Palo Alto, and the remaining two and a half years in San Francisco.

The falling off in the number of students may be attributed partly to the effects of our disciplinary upheaval last year, and partly to the unusual number of failures in scholarship during the second semester of last year.

It should be remembered that the number of students at *Stanford University* is strictly limited.

Syracuse University reports a gain in the fall total of 41 and in the grand total of 42, the summer session showing a decrease of 16, but fewer students having returned for work this fall than was the case last year. A loss of 53 in pedagogy is offset by a gain of the same number in music; the graduate school has lost 23, while the college has gained 29 and architecture 11. Law, medicine, and the scientific schools have remained to all intents and purposes stationary. The entrance requirements in medicine have been increased, so that next fall one year, and in the fall of 1910 two years, of college work will be demanded for admission; the college work to include a competent course in physics, biology, chemistry, Latin and one modern language.

The Lyman Hall of natural history is now fully occupied by the departments of biology, geology and mineralogy, and botany, while the work in chemistry has been transferred to Bowne Hall. The gymnasium will be ready for occupancy at the opening of the second half-year.

The attendance at the *University of Virginia* is exactly the same as last fall, al-

though several changes have taken place in the distribution of the student body by faculties. The decrease in enrollment in the college (24), the scientific schools (11), and medicine (14), may be attributed to increased requirements for admission that became operative this fall. The gain in the law school is due primarily to the fact that the course becomes one of three years, instead of two, beginning with 1909-10. A number of students transferred from the college to law this fall, in order to complete their law course before the new requirement goes into effect. The graduate school has remained stationary. A new course has been established in the engineering department leading to the degree of chemical engineer. An additional wing has been provided for the university's hospital group of buildings; also a commons hall, which furnishes table board to students at cost.

Western Reserve University on October 1 incorporated a pharmaceutical school with 75 students, and has gained 27 students in addition over last year. The academic department shows an increase of 33, all men, while law has gained 9 and the library school (other courses) 7 students. On the other hand, dentistry shows a loss of 12, the graduate school of 5, and medicine of 4 students. The 80 students mentioned under extension teaching are in attendance on standard university courses given in the evening.

Mr. D. C. Mathews, executive secretary, writes as follows:

The opportunities offered by the medical school will be largely increased by the opening of the new H. K. Cushing laboratory of experimental medicine. The department of experimental medicine was made possible by the gift of \$100,000 each by Mr. H. M. Hanna and Colonel Oliver H. Payne. Professor George N. Stewart, formerly of the University of Chicago and recently returned from a year's study in Europe, is head of the department. The building was dedicated on No-

vember 20, the principal address being delivered by Dr. William H. Welch, of Johns Hopkins University.

Work is progressing upon the chemical laboratory on the Adelbert College campus. The building is named for Professor Edward Williams Morley, for thirty-seven years professor of chemistry in Western Reserve.

The Cleveland School of Pharmacy was recently incorporated into the university. The school is now in its twenty-seventh year. The course of study includes thorough courses in general, inorganic and organic chemistry, physics, pharmacy, materia medica, microscopy and physiology. It is proposed to give to the course of study certain larger relationships than its merely technical requirements would demand.

The *University of Wisconsin* reports an increase of 360 students in the fall enrollment, and of 475 in the grand total, the summer session having attracted no less than 376 students more than attended the session of 1907. All of the faculties have contributed to the gain in the fall registration: The academic department 85 men and 42 women, agriculture 72, the scientific schools 26, music 14, law 8, medicine 6, and pharmacy 4 students. The graduate school shows an actual increase of 14 students over last year, although there is an apparent loss of 137. This is due to the fact that the figures for last year included the graduate students who attended the 1907 summer session and did not return for work in the fall; of these there were 151. This year there were 227 graduate students in attendance at the summer session only, so that the total registration of graduate students is 353 for 1907 and 443 for 1908. The first item of double registration (151) is made up of 114 students enrolled in letters and arts, as well as in law, music and medicine, plus 37 students given separately under pharmacy.

There have recently been established a course in chemistry, a course in mining engineering, and a middle course in agri-

culture. The two former are four-year courses, leading to a baccalaureate degree. The last is a two-year course, the entrance requirements for which are the same as those of the regular long course, certificates being awarded at the close, instead of degrees. There has also been organized, within the college of letters and science, a new course for the training of teachers. Within the past year a new central heating plant has been built, as well as an addition to the administration building. A woman's building and a new animal husbandry building are in process of construction.

The increase in *Yale University's* grand total is one of 31, while that for the fall only amounts to 149, the discrepancy being due to the withdrawal of the summer school of this institution; the 48 students mentioned under summer session attended the summer school of forestry. Gains in the fall attendance have been registered by every department with the exception of the academic, which shows a loss of 41 students, whereas the Sheffield scientific school has gained six. To the enrollment of the latter should be added 154 graduate students who are members of the graduate school or the school of forestry. The law school reports a gain of 92, the graduate school one of 51, divinity 26, art 10, forestry 9, music 8, and medicine 5.

RUDOLF TOMBO, JR.

COLUMBIA UNIVERSITY

THE NATIONAL GEOGRAPHIC SOCIETY

THE arrangements for lectures for the current season are as follows:

December 11—"The Redemption of Ireland," by Mr. William E. Curtis. No longer does the Irishman in Ireland live on potatoes and peat. Illustrated.

December 18—"Present Conditions in Turkey," by Dr. Howard S. Bliss, president of the Syrian Protestant College, Beirut.

January 4—"The Sierra Nevada," by Dr. Grove Karl Gilbert.

January 8—"A Digger's Work in Palestine," by Dr. Frederick J. Bliss, author of "A Mound of Many Cities," "Excavations in Palestine," etc.

January 15—"The Non-Christian Tribes of the Philippine Islands," by Dr. Frederick Starr, of the University of Chicago.

January 22—"The Panama Canal and the Spanish Main," by Mrs. Harriet Chalmers Adams.

January 29—"Abraham Lincoln—Boy and Man," by Mr. W. W. Ellsworth, of the Century Company.

February 5—Major General A. W. Greely, U. S. Army, will address the society.

February 12—"The Bird Islands of Our Atlantic Coast," by Mr. Frank M. Chapman, of the American Museum of Natural History. Illustrated with lantern slides and moving pictures of the pelicans and fish hawks.

February 19—"Java—The Garden of the East," by Mr. Henry G. Bryant.

February 26—"Aerial Locomotion," by Mr. Wilbur Wright or Mr. Orville Wright.

March 12—"The Hunting Fields of Central Africa," by Mr. Gardiner F. Williams, for twenty years general manager of the De Beers diamond mines at Kimberley.

March 19—"Ruwenzori, the Snow-crowned Mountain of the Equator," by Professor Edwin A. Fay, of Tufts College, president of the American Alpine Club.

March 25—"Brittany—The Land of the Sardine," by Dr. Hugh M. Smith, deputy commissioner of the U. S. Bureau of Fisheries.

April 2—"Homes for Millions—Reclaiming the Desert," by Mr. C. J. Blanchard, of the U. S. Reclamation Service.

4 BIBLIOGRAPHY ON SCIENCE TEACHING

At a meeting of the executive committee of the American Federation of Teachers of the Mathematical and Natural Sciences held April 28, 1908, it was voted to appoint a committee on bibliography of which Professor Richard E. Dodge, of Teachers College, New York, is chairman.

This committee was requested to prepare, at an early date, a selected and annotated bibliography on science teaching for publication by the federation. The field to be covered includes teaching in elementary, secondary and normal schools and colleges. The list is to

"include books, articles in periodicals, scientific journals or association reports, including foreign contributions, if any." The object is to prepare a bibliography of contributions to science teaching in the last decade "that will be a working basis for any teacher of science and especially for any in an institution with limited library facilities." Since reviews of recent publications on science teaching are valuable in making up programs of study or for meetings, this bibliography should be an aid in this way, and should thus encourage the study of the literature of the subject.

For convenience and effectiveness in covering the whole field of science teaching, specialists were appointed to undertake the work in each of six subdivisions. The cooperators and the work for which each will be responsible are given below:

Mathematics—Professor J. W. A. Young, University of Chicago.

Biology—Professor O. W. Caldwell, University of Chicago.

Physics—Professor John F. Woodhull, Teachers College, Columbia University, and ex-president of New York Physics Club.

Nature Study—Professor M. A. Bigelow, Teachers College, and secretary of the American Nature-Study Society.

Chemistry—Special Committee of the New England Association of Chemistry Teachers.

Geography and Geology—R. H. Whitbeck, State Model School, Trenton, N. J.

It is anticipated that the special reports will be in the hands of the chairman before January 1, 1909, and that the bibliography can be printed and distributed early in the next calendar year.

SCIENTIFIC NOTES AND NEWS

THE convocation week meetings of the American Association for the Advancement of Science, and the twenty-five national scientific societies meeting this year in affiliation with it, have begun at the Johns Hopkins University, Baltimore, as we go to press with the present issue of SCIENCE. We publish above the address of the retiring president of the association, Professor Edw. L. Nichols, of Cornell University, and we hope

to publish next week a general account of the meeting, to be followed in subsequent issues by the addresses and proceedings of the association and the affiliated societies.

THE recently created Royal Society of South Africa has elected Sir David Gill, K.C.B., F.R.S., its first honorary fellow.

DR. WILLIAM EVANS HOYLE, director of the Manchester Museum, has been appointed director of the Welsh National Museum.

DR. F. WALKER MOTT, F.R.S., has been elected Fullerian professor of physiology in the Royal Institution.

CERTAIN friends of the chancellor of Cambridge University desire the establishment of some award to be associated with Lord Rayleigh's name, in order to commemorate the unanimous election of a scientific investigator to the office of chancellor of the university. With this object they have deposited a sum of money, the interest of which may be used for the purpose of awarding from time to time a prize to be called the Rayleigh prize.

PROFESSOR SIR JAMES DEWAR has been elected an honorary member of the German Chemical Society.

THE president of the Cambridge Philosophical Society, Professor Adam Sedgwick, has been appointed to represent the society at the Darwin Centenary celebrations in June, 1909.

THE Broca prize for 1908 has been awarded by the Anthropological Society of Paris, to Dr. Paul Rivet.

THE Godard prize of 1,000 francs has been awarded by the Paris Academy of Medicine, to Dr. F. W. Pavy, F.R.S., consulting physician to Guy's Hospital, London, for his works on carbohydrates and diabetes.

MR. GEORGE H. LOCKE, for the past two years professor of the history and principles of education and dean of the School for Teachers of Macdonald College, McGill University, Quebec, Canada, has resigned to become chief librarian of the Municipal Libraries of the city of Toronto.

JEROME J. GREEN, professor of physics and electrical engineering at the University of

Notre Dame, has taken up his work after a year's leave of absence, which was spent traveling in Europe, visiting the principal educational institutions. He attended lectures at the University of Paris and at the Technische Hochschule in Berlin.

PROFESSOR HUGO MÜNSTERBERG has returned to Harvard University from a trip to Chicago, Toronto and Ithaca. He spoke in Chicago before the Chicago Club on "Psychotherapy," before the Germanic Society on "Books and Readers in Germany and America," and before the Commercial Club on "Psychology in Commerce and Industry." In Toronto he addressed the Canadian Club on "Right and Wrong in the Prohibition Movement." At Cornell University he spoke on "New Developments in the Psychological Laboratory" and "Psychology and Law."

ON January 13, at 4 o'clock, Professor Casius J. Keyser, of Columbia University, will deliver a lecture before the departments of mathematics and philosophy of the Brooklyn Institute of Arts and Sciences on "The Message of Modern Mathematics to Natural Theology."

THE Chicago Chapter of the Sigma Xi Society held its fall meeting on December 9. Dr. Chas. H. Judd, professor of psychology of Yale University and director-elect of the School of Education of Chicago University, gave an address on "Visual Perception and Eye Movements." Fourteen members joined the society at this meeting.

DR. J. B. LEATHES, of the Lister Institute, London, will deliver six lectures on the subject "The Metabolism of the Non-nitrogenous Substances in the Animal Body" in the Carnegie Laboratory of the University and Bellevue Hospital Medical College, New York City, beginning on Monday, January 4, 1909, and continuing daily throughout the week, at four o'clock in the afternoon. Those interested are cordially invited to attend the course.

THE Friday evening meetings of the Royal Institution, London, will begin on January 22, when Dr. Alfred Russel Wallace, O.M., will deliver a discourse on "The World of

Life: as visualized and interpreted by Darwinism."

THE Wilde lecture of the Manchester Literary and Philosophical Society will be delivered on March 9, by Dr. H. Brereton Baker, F.R.S., reader in chemistry in the University of Oxford, the subject being "The Influence of Moisture on the Combination of Gases."

As this year is the jubilee of Speke's discovery of the Victoria Nyanza, the long-sought-for source of the Nile, the Royal Geographical Society commemorated the event by a special meeting on December 14, when Sir William Garstin gave an address on "Fifty Years of Nile Exploration and some of its Results." There was an exhibition of portraits, Speke's original map of his discoveries, and other maps, instruments, photographs, etc.

PROFESSOR THOMAS GRAY, professor of dynamics and engineering at the Rose Polytechnic Institute, eminent for his researches in these subjects, died on December 19 at the age of fifty-eight years.

THOMAS M. WILSON, B.Sc. (Toronto), M.D. (Rush), about to receive the degree of doctor of philosophy at the University of Chicago where he had been assistant in physiology, instructor in pathology in the Chicago Veterinary College, died on November 19 from glanders contracted in the laboratories of the McCormick Memorial Institute in an attempt to produce a serum to counteract the effects of the bacillus of the disease.

PROFESSOR EDUARD G. VON RINDFLEISCH, the eminent pathologist, died at Würzburg on December 5, at the age of seventy-two years.

THE death is also announced of Dr. Giuseppe Ciscato, professor of theoretical geodesy in the University of Padua, at the age of fifty-one years.

ACTING under instructions from President Roosevelt, the Secretary of the Interior has withdrawn from entry, selection and location all public lands in Wyoming, Idaho and Utah believed to contain phosphate rock, pending action by congress.

DR. ARTHUR J. EVANS, F.R.S., has given to the Ashmolean Museum of Oxford University

the collection of Anglo-Saxon jewelry and other relics bequeathed to him by his father, the late Sir John Evans. With it is also a comparative series illustrating the early Teutonic art of the continent, including specimens of Scandinavian, Frankish, Lombard and Gothic work.

It is announced that the collection of implements of the bronze age, formed by Canon William Greenwell, of Durham, will be presented to the British Museum. This collection of implements of the bronze age is regarded as the most extensive of its kind in private hands, and is said to compare well in many respects with that already in the British Museum. It includes specimens from nearly all parts of Great Britain and other countries of Europe, and also from Asia.

THE Royal Society has given to Cambridge University the stellar spectroscopic equipment which has been in the care of Sir William Huggins since 1871. It consists of the following instruments: A refracting telescope with an object glass 15 in. in diameter and 15 ft. in focal length, to which is attached a spectroscope arranged for both visual and photographic work; and a Cassegrain reflecting telescope with a mirror made of speculum metal 18 in. in diameter and about 7 ft. in focal length, to which a spectroscope is attached with optical parts made of Iceland spar and quartz for photographing the ultra-violet spectrum of stars. These two telescopes are mounted equatorially on a single polar axis, in such a way that they can be moved independently in declination. They are at present installed in a dome about 20 ft. in diameter in Sir William Huggins's garden at Tulse-hill. The telescopes and the equatorial mounting were made by Sir Howard Grubb in Dublin, and the spectroscopes by Messrs. Troughton and Simms. The instruments are described as being in excellent working order, and would only require such insignificant changes as are usually needed in passing from one series of observations to another in the ordinary work of an observatory, but a suitable dome will have to be provided for the proper installation of the telescopes.

A PLAN for a new exhibition room on the second floor of Peabody Museum of Yale University has been given up and the restored mastodon is being set up in an exhibition room on the third story. The museum has become so overcrowded that future plans for exhibition have to be restricted. An increasing amount of the space in the building is demanded for scientific laboratories and classroom work.

THE Rev. Joseph Beech, missionary in West China, has presented to the museum of Wesleyan University a collection of ethnological specimens from China and Tibet, which includes about 800 coins and about 300 other specimens. Among these are idols and other objects used in worship, domestic utensils, carvings in jade, ivory and other materials, pictures and books. From the widow of the Rev. Merrill Hitchcock the museum has received Mr. Hitchcock's herbarium.

MR. JAMES GORDON BENNETT has offered the Aero Club of France a new international prize. A cup of the value of £500 is to be competed for next year in France under the auspices of the International Aeronautic Federation and the French Society for the Encouragement of Aerial Locomotion. Besides this cup Mr. Gordon Bennett offers three sums of £1,000 each to be given to the winner of each of the first three annual competitions.

At the monthly meeting of the British Astronomical Association, on November 26, by the permission of the astronomer-royal, the long series of photographs of comet 1908c Morehouse taken with the 30 in. reflector of the Royal Observatory were shown on the screen and described by Mr. Melotte.

As already announced, the Australasian Association for the Advancement of Science will meet in Brisbane on January 11. According to *Nature*, the association will come of age next year, and the meeting will inaugurate the jubilee year of Queensland, the history of which as a separate state dates from 1859. The new president of the association is Professor W. H. Bragg, of Adelaide, while the sectional presidents are Professor Pollock, of Sydney (astronomy, mathematics, and

physics); Professor Easterfield, of Wellington, N. Z. (chemistry); Professor Skeats, of Melbourne (geology and mineralogy); Mr. Charles Hedley, of Sydney (biology); Mr. A. H. S. Lucas, of Sydney (geography); Mr. A. G. Hamilton, of Wellington, N. Z. (ethnology and anthropology); Mr. G. H. Knibbs, of Melbourne (social and statistical science); Mr. H. W. Potts, of the Hawkesbury College (agriculture); Professor R. W. Chapman, of Adelaide (engineering and architecture); Dr. J. Mason, of Wellington, N. Z. (sanitary science and hygiene); Mr. Peter Board, of Sydney (mental science and education). The acting permanent secretary, Mr. J. H. Maiden, can be addressed at the office of the association, Royal Society's House, Sydney, and will be glad to give further particulars and to enroll members for New South Wales.

Nature states that a movement, supported by the Linnæan Society of New South Wales, is on foot to approach the Australian government with the object of having Barrow Island, sixty miles off the northwest coast, set apart as a fauna reserve. The island, which is remarkable for its kangaroo, bandicoot, rat, and wren, none of which occurs on the mainland, is likely to be leased for sheep-farming, to the detriment of the fauna. The policy of the Crown's retention of islands as sanctuaries for wild life is being amply justified by the experiences of New Zealand and the United States, and the Barrow Island fauna is worth effort to save.

THE MORLEY CHEMICAL LABORATORY OF WESTERN RESERVE UNIVERSITY

THE open weather of the fall and winter has made it possible to push more rapidly the construction of the new Morley Chemical Laboratory of Western Reserve University. This building, which will house the departments of chemistry and geology of both undergraduate departments of the university, is situated upon the Adelbert College campus. It will provide accommodations sufficient for three hundred students in chemistry and one hundred and fifty students in geology.

The building is collegiate gothic in style, is

built of brick and concrete, with Indiana limestone trimmings, and is of fire-proof construction. It is three stories in height. The first floor will contain two large laboratory rooms, recitation rooms, offices, small research laboratory, dark rooms, a workshop and storeroom. On the second floor there will be two large laboratories, the main lecture room, with preparation room adjoining, a storage room, a small laboratory, balance room and offices. The third floor will be largely devoted to the department of geology, which department will occupy a large lecture room, a laboratory for students, a private laboratory, offices and a storeroom. This floor will provide, also, additional recitation rooms, library and reading room and a small laboratory for electrochemistry for the department of chemistry. The laboratory building will cost one hundred and twenty thousand dollars and will be ready for occupancy in September, 1909.

The library of the department of chemistry will include the Morley collection of books on chemistry. These books were assembled by Professor Morley during his years of active association with Western Reserve and were given by him to the university. These books are now being reclassified and recatalogued.

UNIVERSITY AND EDUCATIONAL NEWS

THE regents of the University of Wisconsin, in accordance with the recommendation of the State Timber Land Owners' Association and the Wisconsin Conservation Commission, proposed to the United States government to provide a suitable building on the university campus for the use of the U. S. Forestry Service as a laboratory for the investigation of problems connected with the utilization of forest products. The proposed building will cost \$30,000, and will be furnished with heat, light, and power by the university. The U. S. Forest Service desires to concentrate at some engineering college in the west all of its present laboratories. The purpose is to carry on an elaborate series of investigations upon all kinds of timber, with reference to adapting each to its best use, and to utilizing timber, stumps and refuse now wasted. The utilization of the by-products of the logging

operations, the making of wood pulp from various kinds of timber, the distillation of turpentine and other products of wood waste, and similar problems are to be included in the forestry work. The United States government will equip the proposed building at a cost of \$14,000, and will provide the entire staff of investigators, whose salaries will aggregate \$28,000 a year. The laboratory is to be available for advanced university students and instructors in forestry and chemical engineering. The scientific men provided by the forestry service for the laboratory are to give lectures in the university.

THE University of Chicago gives the first two years of the medical curriculum of Rush Medical College, which is affiliated with the university. In order to encourage the spirit and method of investigation among students preparing to study medicine, the university offers three scholarships for the session of 1909-10, to be awarded to applicants presenting the best theses embodying the results of independent investigation in any of the sciences fundamental to medicine—physics, chemistry, or any of the biological sciences. The first prize will be a scholarship for three quarters (\$180), the second prize a scholarship for two quarters (\$120), and the third prize a scholarship for one quarter (\$60). This competition is open to members of the graduating class or graduate students of this college. Theses must be sent to the dean of medical courses, The University of Chicago, on or before April 1, 1909.

ARRANGEMENTS have been made at Lehigh University to keep the conference department open during the Christmas recess. This department, composed of instructors of the university under the direction of one of the professors, is designed to assist students who find difficulty with their current work. It is an innovation in college policy, which is said to have proved a great help since its establishment last September.

By a resolution of the senate of the University of London, it has been decided to ask the government to appoint a royal commission with a view to the introduction of a bill to

secure incorporation of the Imperial College of Science and Technology with the University.

WE are informed that the note given prominence by the New York papers and reprinted in SCIENCE to the effect that Governor Johnson had asked President Roosevelt to accept the presidency of the University of Minnesota is incorrect.

DR. ADAM SEDGWICK, professor of zoology at Cambridge, and fellow at Trinity College, has accepted a professorship of zoology at the Imperial College of Science and Technology, London.

At the University of Glasgow, Dr. Cecil H. Desch, of University College, London, has been appointed to the Graham Young lectureship in metallurgical chemistry to succeed Dr. C. E. Fawsitt, who resigned to accept the newly-established chair of chemistry in the University of Sidney, N. S. W.

DISCUSSION AND CORRESPONDENCE

THE "PINCH-EFFECT" IN UNIDIRECTIONAL ELECTRIC SPARKS

PROFESSOR NIPHER has recently described¹ some interesting experiments on momentum effects in electric discharge, and writes as follows concerning the unidirectional sparks obtained by the insertion into the circuit of strips of cloth moistened with a saline solution:

... the sparks are large and brilliant at the negative end in both positive and negative lines, and thin out towards the positive end. The negative terminals are large spheres of about 10 cm. diameter. The positive terminals are small knobs, of about 1 cm. diameter. *While on the large sphere the electrons repel each other. But when they start into motion across the spark-gap, they attract each other electromagnetically.* This appears to be the reason why the spark thins out as the electrons proceed in their motion across the spark-gap. [The italics are mine.]

According to theory, two like charges repelling each other when at rest, begin to develop an electromagnetic attraction for each other as soon as they are put in motion in the same direction. But this attraction does not be-

¹ SCIENCE, December 4, 1908, p. 807.

come equal to the electrostatic repulsion until the charges move with the velocity of light. This used to seem very puzzling to me, for I reasoned as follows: Imagine a positively charged hopper filled with steel balls, which continually dropped into two parallel inclined glass troughs. As the motion of the charged balls is constantly accelerated, the electromagnetic attraction which they exert on the charged balls in the other trough grows larger and larger until the velocity is that of light, when the streams of balls in the two troughs are exerting zero force on each other (for their electrostatic repulsion is then exactly balanced by their electromagnetic attraction), and yet they are said to be behaving like electric currents. Why, then, do parallel currents actually attract each other? No one supposes that a current in a wire travels *faster* than light. Some years ago in Cambridge I asked Professor (now Sir) J. J. Thomson about it, and he replied that my analogy was all right, except that according to the electron theory the glass troughs should have a metal covering outside, which is *positively* charged, the hopper should be *negatively* charged, and the positive charge on a unit's length of a trough should equal the sum of the negative charges on the balls contained in that length. Then the analogy, while crude, would be complete: the steel balls would represent electrons, and the current in the ordinary sense would flow *up* the trough instead of down. The charge on the metal covering of the trough would represent the charges on the positive atoms in a conductor. Under these circumstances it is easy to see that attraction between the troughs would ensue as soon as the balls began to move. Professor Nipher's explanation, therefore, would seem to be valid only on the supposition that the positive ions in the line of the disruptive discharge (which are dashing towards the negative terminal) would take the place of the metal-covered trough in my analogy, thus rendering the electromagnetic attraction of the moving electrons effective in drawing them together in a column which continually thins out towards the positive terminal. If this be true, the effect ought to be rendered

more intense because of this consideration: the analogy would then be that of the trough itself (carrying a positive charge) *moving in the opposite direction to the motion of the steel balls*, thus making the relative velocity of the balls greater and the attraction more intense.

But there is another way of looking at it which may be more natural. The negative terminal is a large sphere 10 cm. in diameter, while the positive terminal is but 1 cm. in diameter. The lines of force are therefore strongly convergent from the negative to the positive sphere, somewhat like the ropes from the gas bag of a balloon to the much smaller basket beneath, and electrons sliding down these lines (along their negative direction, of course) would naturally arrange themselves in a column larger at the negative end, especially as these lines are themselves falling towards the center line of the discharge. In this case would not the phenomenon simply show the pinch effect in gaseous discharge?

ANDREW H. PATTERSON

UNIVERSITY OF NORTH CAROLINA,

December 7, 1908

MR. MANSON'S THEORY OF GEOLOGICAL CLIMATES

MR. MANSON'S theory of geological climates has been commended latterly in the columns of SCIENCE and elsewhere, and it may be desirable to point out why it is unsatisfactory.

The theory as set forth in Mr. Manson's communication to the Tenth International Geological Congress, in Mexico, in 1906,¹ is briefly as follows: During Paleozoic time the climate of the earth was practically uniform from equator to poles, and torrid temperatures were everywhere maintained by heat derived from the earth and warm oceans; the heat was prevented from radiating into space and being lost by a blanket of clouds surrounding the whole earth. Recognizing that the heat brought to the earth's surface by conduction is not enough to keep up a high atmospheric temperature, Mr. Manson thinks that much heat was made available by the erosion of the land and by hot springs, volcanic eruptions, etc. Let us calculate how much heat can be

¹ *Proceedings*, Vol. I., pp. 349-405.

obtained by this means, and in making this calculation we give every possible advantage to the theory. Let us assume with Dr. Becker² that at the time of consolidation the surface of the earth was at a temperature of 1300°C ., and increased at a uniform rate at least to a depth of 0.02 of the radius or 126 kilometers, and that up to the present time no appreciable change of temperature has taken place beyond that depth. Let us further assume that the surface has been reduced to 0° and that the present temperature gradient is a straight line from the surface to a depth of 126 kilometers. The average loss of temperature within this shell is $1300/2$ or 650° , and if we take the specific heat per cu. cm. as 0.5 calories, the total heat which has been lost per sq. cm. of surface is $12,600,000 \times 650 \times 0.5 = 4.1 \times 10^9$ calories. This is a very liberal allowance.

Assuming an ocean 5 kilometers deep covering the whole earth, whose original temperature was 40°C . and which has cooled to 0° , the total heat given out per sq. cm. of surface would be (specific heat per cu. cm. = 1), $500,000 \times 40 = 2 \times 10^7$ calories. This is only one half of 1 per cent. of the heat furnished by the land and may therefore be neglected.

The heat at present being received from the sun equals 2 calories per sq. cm. per minute, measured at right angles to the sun's rays.³ As this falls on the section of the earth it must be divided by 4 to give the average amount on the earth's surface. Let us suppose, further, that three fifths of the remainder is lost by reflection and other causes and does not heat the earth's surface. This leaves 0.2 calorie for the average amount received by 1 sq. cm. of the earth's surface per minute; and in one year the total amount received would be $0.2 \times 60 \times 24 \times 365 = 10^6$ calories, and as the earth has a practically stationary temperature it is losing this much heat per year by radiation into space. At this rate all the heat lost from the earth since consolidation could only keep up the present average temperature for a number of years equal to $4.1 \times 10^9 / 10^6 = 41,000$ years; but if on account of the cloud-blanket only 10 per cent. as much

heat is necessary to maintain the temperature it would last 410,000 years; if only 1 per cent. were needed, it would last 4,100,000 years, a period much shorter than pre-Mesozoic time.

But what would establish and maintain a blanket of clouds around the earth, and especially over great inland regions like the centers of Africa and Asia? The only places where clouds are now prevalent are places in high latitudes where moisture is continually precipitated from the winds which blow pretty steadily from warm seas; but even with our present atmospheric circulation the interior of the great continents are rather dry. With the uniform temperature which Mr. Manson predicates in Paleozoic time there would be no winds, and the sun would soon break up the cloud-covering over the interior of the continents, as there would be no steady supply of moisture. Moreover, an atmosphere heated at the bottom is in unstable equilibrium, and convection currents would be set up which would carry the moist air to high altitudes and result in heavy downpours of rain and a clearing of the atmosphere; for the available heat would be entirely inadequate to supply moisture to form clouds as fast as it would be precipitated as rain. The existence of clouds would have no influence on the convection currents. Mr. Manson mentions these currents, but does not attach any great importance to them.

It is to be noted that geologists who have given attention to the earlier glacial periods do not consider that they were due merely to small glaciers at high altitudes, but that they represented real, even if not very extensive, changes in climate. Moreover, Professor J. W. Gregory firmly maintains that throughout geological times we have had a zonal distribution of temperature very similar to that of the present day.⁴ It is therefore, quite possible that the continued uniform climate which Mr. Manson's theory was developed to explain, did not really exist.

Professor Schaeberle⁵ approves Mr. Manson's theory and states that "The inherent

heat of the earth still plays an important if not controlling part in all terrestrial phenomena. . . ." This idea is based on an earlier communication* whose conclusions are invalidated by his erroneous definition of temperature and by his erroneous assumption that a body placed in a stream of radiant energy has its temperature raised by an amount proportional to the quantity of radiant energy falling upon it in a unit of time.

It can readily be shown that the heat received by conduction from the earth is insignificant in comparison with that received from the sun, as was long ago done by Lord Kelvin. The quantity of heat reaching the earth's surface per minute through each sq. cm. equals the conductivity of the rock multiplied by the temperature gradient multiplied by 60 seconds. If we take the conductivity of rock at 0.005 and the temperature gradient at 0.00032° C. per cm. (which corresponds to 1° C. per 31 m. or 1° F. per 50 feet) we find 9.6×10^{-3} for the quantity of heat conducted to the surface per sq. cm. each minute, and since we can take the quantity received from the sun for the same area in the same time as 0.2 calorie, we see that the earth's surface receives from the sun at least 2,000 times as much heat as from its interior. The latter, therefore, could not have a material effect on the surface temperature or on atmospheric phenomena.

ON MISLEADING STATEMENTS

SINCE misleading statements occur in the publications of certain writers concerning my participation in, and experimental contributions to the subject of blood-vessel anastomosis and transplantations, in justice to myself and in the interest of investigators in general, it is incumbent upon me to perform the disagreeable task of making a statement once for all, that the facts may be made readily accessible. The task will be made easier if I am permitted to quote rather freely.

Carrel in a paper appearing in the *Journal of the American Medical Association*, November 14, 1908, LL, p. 1864, says:

* *Science*, December 20, 1908, p. 877.

The transplantation of devitalized arteries has been attempted by Levin and Larkin in New York, but in almost every case thrombosis occurred. However, after the transplantation of a segment of aorta fixed in formalin into the aorta of a dog, excellent circulation was observed. Histologic examination ten days after the transplantation showed that the wall was composed of amorphous tissue in which the elastic framework was seen to be very well preserved. In another case of Levin and Larkin, twenty days after the operation, the wall of the vessel was completely amorphous and surrounded by dense connective tissue. A similar experiment has been performed in St. Louis by Guthrie, who obtained an excellent functional result, but no histologic examination of the vessel has yet been published.

Levin and Larkin, in *Proceedings of the Society for Experimental Biology and Medicine*, 1907-8, V., p. 110, say:

On January 23, 1908, we transplanted a segment of aorta from a dog hardened in 4 per cent. formalin into the abdominal aorta of another dog. Meanwhile Guthrie reported successful implantation of formaldehyde segments into the carotid of the dog.

The facts regarding the transplantation of formaldehyde-fixed segments are as follows: In the *American Journal of Physiology*, September 2, 1907, XIX., 482-7, in the paper entitled, "Heterotransplantations of Blood Vessels," I stated:

In this connection it may be mentioned that a segment of aorta from a cat preserved in formaldehyde for about a month, then washed in very dilute ammonia water, partially dehydrated in alcohol and impregnated with vaseline, when similarly transplanted into a dog gave excellent temporary results. On killing the animal with ether and examining the segment, it was found to resemble the artery of the dog in a much greater degree than before being transplanted, being more pliant and having a flesh color, the latter due, no doubt, largely to the presence of blood that got into or between the coats from the outside. The union of the intimas was excellent, and they both had the characteristic glistening appearance. My thanks are due Dr. Bartlett for assistance with this operation. A series of operations are being made with the view of determining the permanent results of similarly prepared and transplanted blood vessels.

My records show that this experiment was performed June 20, 1907. In *SCIENCE*, N. S.,

March 20, 1908, XXVII, p. 473, is reported the successful transplantation of a formaldehyde-fixed segment of blood vessel into a dog. Since the work had been announced in 1907 in the article referred to above, I did not consider it necessary or even of interest to state the date of the successful operation. Since this appears to have been a mistake on my part, I desire for the benefit of those interested to here record it. My record shows that the operation reported was performed January 22, 1908. On February 12, 1908, the neck was opened and the segment directly examined. On February 29, 1908, the animal was demonstrated before the St. Louis Medical Society.¹ The manuscript of the note in SCIENCE was mailed to the editor February 17, 1908.

Levin and Larkin in *Proceedings of the Society for Experimental Biology and Medicine*, 1907-8, V., 109, also say:

Carrel demonstrated that it is not only possible to unite the two ends of a severed artery by a suture but also to interpose between the cut ends of it a segment of an artery of another animal and perform a double anastomosis. *The success of the operation is due to the fine technique elaborated by Carrel.*²

The following quotations from a paper entitled, "Uniterminal and Biterminal Venous Transplantations," by Carrel and Guthrie (from the Hull Physiological Laboratory, University of Chicago), *Surgery, Gynecology and Obstetrics*, March, 1906, II, pp. 266-77, will furnish those interested food for thought:

The transplantation of veins is a new operation, and has been largely developed in this laboratory. Therefore its history is short.

In 1902, however, Carrel had shown that arterio-venous anastomoses were possible, and considered that all the transplantation of veins were feasible. Our present results have entirely confirmed this opinion.

In 1905 we began experimenting in this laboratory³ with the view, among others, of making a

¹ *Interstate Medical Journal*, XV., No. 6.

² The italics used in the above quotations are my own.

³ The work in this laboratory has been conjointly performed.

complete study of the transplantation of veins. Several series of experiments were undertaken in order to study the results of the uniterminal and biterminal venous transplantations, and they were thoroughly successful. At this point we wish to thank Dr. Stewart for his interest in this work and his valuable suggestions, which have contributed in no small degree to its success.

In order, therefore, to successfully transplant veins on to the arterial system, it was necessary to have a technique permitting the union of the vessels without hemorrhage or thrombosis. Besides, positive results must be constant, for a method is not satisfactory otherwise. In the first experiments (1902), the technique employed did not always yield good results. Thrombosis often occurred. This was due mainly to the fact that the delicacy of the endothelium of the vessels was not appreciated. This led to a realization of the fact that ordinary surgical methods are inadequate. The methods, for instance, which give splendid results in abdominal surgery are much too rough for use in vascular surgery. The surgery of the blood vessels is a new and special field, and the operative handling must be delicately adjusted and adapted to the nature and the reactions of the tissues.

According to these considerations, our technique was improved by degrees. The threads and the needles were the finest and the strongest obtainable. The threads were sterilized in vaseline, and applied when heavily coated with the same. The vessels were handled very gently, and the endothelium was protected from drying by isotonic sodium chloride solution or by sterilized vaseline. No dangerous metallic forceps were used. The greatest care was exercised to obtain accurate and smooth approximation of the endothelium of the vessels. Finally, we developed a technique which is equally well adapted for arterio-arterial, venovenous, or arterio-venous anastomoses, and which yields uniformly successful results.

This new technique has been used since August, 1905. Numerous arterio-venous anastomoses and transplantations of veins have been successfully performed. Union of the walls of an artery and a vein to each other may be made without the subsequent occurrence of hemorrhage or stenosis.

Modesty should prevent, but I am unable to refrain from remarking in passing that it is a singular fact that up till the time Carrel and I engaged in the work together he reported that his experiments did not always

yield good results, and that *our results almost from the beginning of our work together were excellent!* Indeed, so far as I have been able to determine, Carrel working first with Berard, then with Morel in France, and later by himself in Dr. Carl Beck's laboratory in Chicago, claims only one permanently successful result.* This was an arterio-venous anastomosis made with Morel between the jugular vein and carotid artery of a dog. The animal was under observation but a short time and ultimately was lost, so no direct examination of the result was made. But in all probability it would have remained good. He attributed his earlier unsuccessful results to "poor asepsis," but since I have observed that moderate infection is of slight importance as regards the result which such blood vessels as he used are united by the methods perfected by him and myself, this, it would seem, is not the full explanation. As to priority, it gives me great pleasure to express my high regard for Dr. Carrel's persistence in the face of a long series of unsuccessful operations and I desire to in no way endeavor to attach any of the credit he deserves for this devotion.

Many experimenters have endeavored to sew together openings in blood vessels and to unite them end-to-end. To verify this statement one need only to refer to a modern work on surgery, *e. g.*, "American Text-book of Surgery," 1903, p. 292. Murphy, himself the author of a successful method of end-to-end anastomosis—a method used successfully on man—gives a short but valuable summary of the literature,[†] beginning with the successful suture of a longitudinal incision in an artery in 1762 by Broca.

The dubious distinction of *priority* which it would appear is the goal sought by some of our contemporaries, presents slight attraction to the sincere investigator whose reward largely is the consciousness that his labors may in the end add a line to the encyclopedia of science.

* See *Surgery, Gynecology and Obstetrics*, March, 1906, II., p. 269.

† "Resection of Arteries and Veins Injured in Continuity—End-to-End Suture," *Medical Record*, January 16, 1897.

In addition to the references given above a list of the more important papers published conjointly by Carrel and the writer is appended:

WILLIAM KEITH BROOKS

TO THE EDITOR OF SCIENCE: Allow me to call attention to several errors that appeared in my sketch of William Keith Brooks, in *SCIENCE*, for the fourth of December, 1908. On page 777 Brooks's college education is ascribed to his own exertions, but in fact not only did his parents put no obstacles in his way but his father sent him to Hobart College and later to Williams College. It was only his subsequent, post-graduate training, that required Brooks's own labors. Moreover, it is doubtful if his experience in his father's counting-office was not after he had finished his college education. Again on page 778 Hobart College is confounded with the De Vaux College, a school for boys near Niagara Falls. It seems that Brooks was a student at Hobart, entering in 1866, and leaving at the end of his sophomore year to go to Williams College, where he graduated in 1870. Subsequently he taught, as one of the masters, at De Vaux College, from 1870 to 1873. On the same page Tyron should read Tryon and H. Tuttle, Albert H. Tuttle.

E. A. ANDREWS

SCIENTIFIC BOOKS

A Key for the Determination of Rock-forming Minerals in Thin Sections. By ALBERT JOHANNSEN. New York, John Wiley & Sons. 1908.

This key has been prepared, as the author states, for the reason that tables for the optical determination of minerals in thin sections have heretofore been made of secondary importance in text-books. Most of the books on this subject, while admirable in their way, are of more use to trained mineralogists than to beginners, this being due principally to the absence of "classification."

The book is divided into four parts: Part I. treats of introductory optics, measurements to be made with the microscope and the methods of recognizing the common optical characters of minerals. Part II. takes up the general discussion of the relations between the different members of the common groups of minerals. Diagrams are here given to assist in the determination of the species in the pyroxene, amphibole and feldspar groups. The part treating of the feldspars is particularly elaborate, giving fourteen methods of investigation. Part III. (415 pages) gives an explanation of the tables and contains a very elaborate scheme for determination, based on a systematic identification of the fundamental optical characters of the minerals in question, the minerals with similar optical characters being grouped in the same part of the scheme. Following the description of each mineral are given the distinctions between it and other similar minerals. Part IV. contains tables of mean indices of refraction, maximum birefringences, specific gravities, and also lists of minerals by crystalline system and "habit." A summary is appended of the optical characters of the minerals in alphabetical arrangement, which is very convenient, as it does away with the necessity of remembering the author's special arrangement, a universal fault to be found with other tables.

This book represents a very elaborate and painstaking collation of the important optical and crystalline characters of some one hun-

dred and sixty-four rock-forming minerals, and, for the first time in the literature of the subject, the minerals have been arranged in a way for systematic optical determination. A further advantage lies in the fact that these optical and crystalline characters are always recorded in the same order and that paragraphing is freely used. The author has made the introductory discussions on optics and determination of optical characters as simple as possible, but has given detailed foot-notes referring to more complete theoretical discussions of the underlying principles. Standard authorities have been consulted in the preparation of the general data, but the tables might have proved more useful had authorities been cited.

The scope of the work along optical lines is similar to that covered by Penfield and Brush in their "Tables for Blowpipe Determination of Minerals."

The scheme is sufficiently elastic to provide for mistakes likely to be made in the determination of some of the optical characters, as for example, extinction angles. Minerals with small extinction angles (under 5°) are found in two places of the scheme, both with minerals with inclined extinction and with those with parallel extinction. The micro-photographic cuts of interference figures are very good and many of the tests are explained with the aid of detailed diagrams, so that they may be easily and quickly made. A good color chart of the interference colors (after Lévy and Lacroix) is appended.

The value of the book might have been increased by a more detailed description of the types of petrographical microscopes and their common adjustments. Also the suggested indenting of the pages of the text is a matter of much trouble and an arrangement providing for this being done by the printer would certainly prove of great advantage in subsequent editions.

L. MCL. L.

Southern Agriculture. By F. S. EARLE. Pp. vi + 297. Containing 9 half-tone plates, many text cuts, and full index. New York, The Macmillan Co. 1908.

This work has many points of merit to commend it to the schools of the south and will no doubt be widely used as a text-book. It is divided into two parts, the first dealing with general considerations, such as climate, soil, soil management, soil improvement, the growth of plants, insects and diseases, and closes with a chapter on farm policy and management. The second part treats of the chief southern agricultural crops, including grasses and forage crops, fiber crops, tobacco, coffee, fruits, nut crops and forestry, and closes with a short chapter on domestic animals.

In the chapter on management of the soil, valuable suggestions are given on the use of farm implements, a part of agriculture so often neglected by writers. A little farther on, soil improvement is well treated and the relation of leguminous crops to same, with recommendations of certain leguminous crops for certain kinds of soil. The student is shown the relation of the plant to the soil, and the functions of the different parts of plants. The chapter on spraying and sprays, containing formulæ for different sprays, is well arranged and almost indispensable, inasmuch as crop enemies such as insects and fungi are so rapidly increasing in the south where heat and moisture are so conducive to their welfare.

In treating of individual crops in the second part of the book, the method is to be commended. First the author deals with the crop itself, and then as far as consistent with the nature of the plant, takes up a detailed study in each individual crop, of soil and climate, manuring, methods of planting and cultivating, and harvesting. This uniformity of method gives the pupil the benefit of comparing one crop with another on any of these points suggested.

Just what is meant by southern agriculture is not suggested by the author, but from the numerous references to the tropics and to tropical agriculture, it would seem that they are included in the title of the book. Possibly it would have been better to have gone a little further into the general and specific methods of tropical agriculture, and have

given the book the title "Southern and Tropical Agriculture."

There seems to be very little excuse for devoting twenty-four pages to sugar cane and only sixteen to cotton, when the author states that cotton is our "greatest commercial crop," also, only twelve to corn, "the most important crop." A little more space should have been devoted to the best methods of improving cotton and corn, if not any less to sugar cane, especially after the above statements. The space devoted to an explanation of the poor methods of cotton planting on pages 175 and 176 could have been better used by giving better methods and emphasizing the necessity for level cultivation of cotton. It is a better paying business, for instance, to lay off new rows for your cotton than to follow cotton after cotton, as suggested in the text, notwithstanding the fact that its danger is hinted at on the same page.

There is no chapter devoted to the dairy and live-stock industry, though the importance of it is suggested in three places in the book. Stock feed can be raised very cheaply in the south and the cost of keeping stock is reduced to the minimum. No costly shelters are required, and it is possible to arrange your pastures so that your stock can graze ten or eleven months in the year. Besides, at present we ship from the south millions of dollars' worth of cotton-seed meal annually, to be used for stock feed in other parts of the world, instead of using it as we should, first through live stock to increase the beef and butter production of the south, and secondly in the form of barnyard manure to fertilize the land with. It is believed that the book would have been worth more to the schools of the south, if a good, lengthy chapter on the live-stock industry had been included.

In conclusion, it seems that the author is more at home in his studies of tropical agriculture, and though he has done excellent work, many parts of the book read as if the information given were not first hand. For instance, there is a freshness and an air of confidence in those parts that treat of diseases and remedies, and the botanical features of special crops that are conspicuously lacking

in the parts devoted to manuring and cultivating.

R. J. H. DeLoach

Bermuda in Periodical Literature, with occasional References to other Works. A Bibliography by GEORGE WATSON COLE. Pp. ix + 275. Printed for the Author. 1907.

This volume contains 248 pages of references and 24 pages of index; the references are arranged alphabetically by publications, the index by subject and author, thus providing easy access to the contents. Each title is followed by a brief note which gives the characteristic features of the article, and these notes constitute a feature quite as valuable as the references themselves.

On the last page is a list of references to libraries in which a copy of the work cited was found. By the choice of fonts and skillful use of insets the various items of a citation are clearly differentiated to the eye, and the page is made attractive. The range of periodicals cited is very wide, and they cover not only newspapers and magazines, but proceedings of learned societies. The range of subjects is unrestricted, and taken together, they comprise nearly all that has appeared concerning history, description and natural history for the last fifty years. The last division has been especially well done, for it became apparent to Mr. Cole, soon after beginning his compilation, that Bermuda has been a favorite field for the geologist, the botanist and the zoologist. In the preface he says:

Bearing this in mind, a special effort has been made to render the record of their labors as complete as possible. In order to do this, references are made to some works which are not periodicals, mostly, however, by authors who have also made contributions to periodical literature concerning the flora and fauna of those islands.

The result of this special effort has been to provide in one volume a reference to nearly every addition made to the flora and fauna since (and including) the *Challenger* expedition. The value of such a gathering to the botanist and the zoologist can not be overestimated, and this compilation, moreover, has proved to be exact and accurate at every point,

tested by the reviewer. Some idea of the manner of treatment may be gathered from the fact that nearly fourteen pages are required for the direct excerpts from the *Challenger* report, to say nothing of the entries of articles appearing elsewhere on the *Challenger* material. The references on birds go back to 1849 and come down to 1904; those on flora extend from 1700 to 1906; those on geology from 1833 to 1906. Moreover, the index takes account of the changes in nomenclature (*e. g.*, "Leptocardians, Goode (1877), 19. See also *Asymmetron*"), so that the difficulties due to this unfortunate obstacle are minimized.

While natural history is amply represented, the other subjects are not neglected. Twenty-four pages are given to citations from the New York City daily papers and seven pages to those from the London *Times*. The total number of citations is 1,382.

Taken as a whole, the work is a masterpiece of bibliography. To take up the chronicles of a somewhat remote island and set them down in order in these days of wide-spread publication seems a task almost impossible to perform in a creditable manner, and a thankless task when done. Mr. Cole's work is excellently well done, and he will earn the hearty thanks of every botanist and zoologist who has occasion to use the volume. In view of the forthcoming tercentennial celebration to be held in Bermuda next year, the colony may well thank Mr. Cole for so handy a volume of reference.

C. L. BRISTOL

SCIENTIFIC JOURNALS AND ARTICLES

Terrestrial Magnetism and Electricity for December contains the following articles: "Solar Magnetism," by W. J. Humphreys; "Note on the Magnetic Effect of Winds," by W. J. Humphreys; "Solar Magnetic Fields and the Cause of Terrestrial Magnetism," by W. Sutherland; "Note on Sutherland's Article," by G. E. Hale; "On the Probable Existence of a Magnetic Field in Sun-spots," by G. E. Hale; "On the Distribution of Magnetism over the Earth's Surface, II," by P. T. Passalskij, translated by Paul Wernicky;

"Results of Recent Magnetic Observations in Mexico (1906-8)," by Felipe Valle; "The Magnetic Storms of September, 1908," by O. H. Tittmann; "Letters to Editor," "Notes," etc.

THE NEWEST ANCIENT MAN

Yesterday (December 14) before the Academy of Sciences Professor Edmond Perrier, director of the Museum d'Histoire Naturelle exhibited a skull to which he ascribes a great importance. The skull, together with other parts of the skeleton (bones of the upper and lower limbs), was found about six months ago by two abbés (Bouyssonie and Bardon) in some excavations being made near Chapelleaux-Saints in the Corrèze.

The rock strata in which these bones were found are, according to M. Perrier, of middle Pleistocene age.

The skull is that of a man of extremely low type, an ape-man, or perhaps of a man-ape of greater cranial capacity than any at present known. This great cerebral development leads M. Perrier to consider it, on the whole, a human skull. But the very thick, low cranial dome, the flattened forehead and pronounced orbital ridges, the broad nose separated from the forehead by a deep furrow, and the much elongated snout-like maxillaries combine to give the skull a marked gorilla-like seeming. The brain cavity, however, is as already said, very much larger than that of the gorilla or any other present-day anthropoid.

The limb bones are curved and present a conformation which indicates that this Pleistocene man walked more often on all-fours than in an erect position. The bones seem to be fairly intermediate between those of a man and those of the present-day anthropoids.

Altogether Professor Perrier (whose scientific standing gives his opinions in the matter high authority) believes that he has in his hands—the specimens have been purchased by the museum—remains much more ancient than those of Neanderthal or Spy, and actually representing a type intermediate between Pithecanthropus and present man.

Those interested should watch for the more detailed and authoritative report of Professor Perrier's account which will appear in the *Comptes Rendus*.

VERNON L. KELLOGG

PARIS,

December 15

THE INDIANA UNIVERSITY EXPEDITION TO BRITISH GUIANA

PROFESSOR CARL EIGENMANN, dean of the Graduate School of Indiana University, has just returned from a four months' trip to British Guiana, where he was engaged in the study and collection of South American fishes. He was accompanied by S. E. Shideler as a volunteer assistant. Professor Eigenmann is now engaged in a monograph of the freshwater fishes of tropical America. The trip to British Guiana had three objects. It was intended to collect as many species of freshwater fishes as possible from one of the South American rivers flowing north; to photograph living fishes, and to collect on the plateau of Guiana.

Fishes were collected near the mouths of rivers from the Berbice River on the east to Morawhana near the Orinoco on the west. In the Demarara River collections were made at Georgetown, at Nismar, near the head of tide water, about sixty miles from the coast, and at Malali, almost thirty miles further up stream at the first rapids.

In the Essequibo River collections were made at Bartica, Rockstone, Crab Falls and the Warraputa Cataract.

For an attack on the Guiana Plateau the Potaro River was selected. It is a tributary of the Essequibo about ninety miles from the coast. There are a series of short cataracts with long stretches of navigable water in between. The first of the rapids are at Tumatumari where extensive collections were made. From the next rapids, near Potaro Landing a path of seven miles brings one above the Ichaura, Aurituk, Cobanatuk and Pakatuk Cataracts to Oangaruma. From here on the trip was continued with the boats and crew of sixteen Indians, generously put at the service of the expedition by Messrs. G. Linnel and

Edward Bovalius of the Essequibo Exploration Company.

Progress above Cangaruma was retarded slightly by fever. A portage at Amatuk and another at Waratuk with two days paddling brought the expedition to Turkeit at the base of a series of Cataracts at the head of which is Kaieteur Fall, the show place of British Guiana. The Potaro here leaps 741 feet from the plateau to the Potaro Gorge below.

A portage of 2½ hours carries one from Tukeit to the Savannah above the falls. Mr. Schideler returned from this point to collect near the coast, while Professor Eigenmann continued with thirteen Indians to Holmia and Arnataima, the first cataract above Holmia.

Thorough collecting was undertaken in the Potaro above and below the Kaietue with the use of hooks, seines, dynamite and most effectively with Haiara, the poison used by the natives in their fishing. The expedition was thoroughly satisfactory although few photographs of fishes could be taken on account of the labor necessary to secure suitable specimens.

It is hoped that it will be made possible to continue the exploration of the Guiana Plateau which sends rivers over heavy falls to the Essequibo, Orinoco and Amazon from around Roraima, possibly the oldest land area of South America.

The bit of most satisfactory discovery is that *Gasteropelecus*, an aberrant characin, flies. This fish has the most amazing structure for a characin. It possesses huge pectorals, a tremendous "sternum" and pectoral muscles to correspond. It was frequently seen to dart from in front of the boat, float its pectorals while part of its tail and sternum remained in the water and then in the last five or ten feet of its 45-foot flight clear the water. As long as part of the fish remains in the water the pectorals touch the water with each stroke. Not the least interesting fact is that their line of evolution from generalized Characins is indicated by the still-existing genera like *Chalceus* and *Pseudocorynosoma*.

SPECIAL ARTICLES

SPECTRUM OF COMET MOREHOUSE

THE spectrum of this comet has been under observation here since October 28, with the use of a Zeiss photographic doublet of 145 mm. aperture and 81 cm. focal length, made of "ultra-violet" glass, over which was placed a 15° objective-prism of the same glass and aperture. With an exposure of fifteen minutes the head of the comet then gave a sufficiently strong impression, showing a row of seven knots. With longer exposure the tail could be well traced from some knots until it ran off the plate, at a distance of 3°.

The absence of a continuous spectrum was striking, and on no plate thus far obtained has it been certainly visible. This indicates that during this period the reflected light has been exceedingly weak in both head and tail relatively to the intrinsic light due to the carbon and cyanogen bands.

A very small quartz spectrograph was also attached to the same telescope, and plates having the advantage of a comparison spectrum were obtained on four nights. Twenty-one satisfactory plates were obtained with the objective-prism on eleven dates. All the plates were made by Parkhurst, with assistance, when necessary, from Frost.

The measurements of wave-length are quite uncertain on account of the very small scale of the spectrum with either apparatus—only 2.5 mm. from $H\beta$ (λ 4861) to $H\theta$ (λ 3798) with quartz spectrograph (3.0 mm. with objective-prism)—but we have been surprised at the accordance of our measures on different plates. It is difficult to make settings on the edges of the cometary bands on account of their diffuseness, so that it is often necessary to be content with settings on the centers of the knots.

We regard the identification as certain for the third and fourth carbon bands (edges at λ 5165 and λ 4737) and the first, third and fourth cyanogen bands (λ 4601, 3883, 3590). These carbon bands are two of the three bands characteristic of cometary spectra, and often, perhaps generally, ascribed to a hydrocarbon. The other one, at λ 5635, did not affect our

plates. We have measured other bands as follows:

Extending from about λ 4290 to λ 4260 with center at λ 4267.

Extending from λ 4030 to λ 3995 with center at about λ 4015.

Center at about λ 3915, less refrangible edge at about λ 3920.

Center at about λ 3795.

Those at λ 4267 and λ 3920 fall in the position of the only lines (as contrasted with bands) in the carbon spectrum in this region, but we do not regard this as an identification.

The tail extends out in very different intensities from some of the knots: thus λ 4737 has only a small extent of tail, but the knots at λ 4737 and 3883 give the appearance of a greater development than the others in the direction away from the tail, i. e., toward the front of the head.

Otherwise the spectral images of the tail exhibit the same general structure shown by direct photographs of the comet on the same nights. No marked changes in the chemical constitution of the tail have been observed by us between October 28 and December 1. It is interesting to note, however, that this simple apparatus would have been competent to show any differences in constitution such as called for by Bredichin's theory, had it been used on September 16, when the direction of the tail changed through a large angle from its direction before and after that date.

A detailed account of our study of these plates, with reproductions of some of them, will appear later in the *Astrophysical Journal*.

YERKES OBSERVATORY,
December 2, 1908

A SIMPLIFIED APPARATUS FOR DRAWING WITH THE AID OF THE PROJECTION MICROSCOPE

In a number of laboratories there are in use devices for drawing by the aid of a projection lantern. These vary in complexity from a simple easel at which is traced the direct projection of the image, to comfortable dark rooms especially equipped for this work and with an apparatus for reflecting the image to

the table at which the artist sits. The first type is inconvenient and fatiguing, the second, on account of both the expense and the space demanded, is not available in every laboratory. It was Professor S. H. Gage's complete and excellent equipment that suggested the here-described simple device, to be used in the lecture-room where the projection outfit stands, without duplication of apparatus or requirement of extra space.

It consists merely of a rod holding a mirror at an angle of exactly 45° , clamped to the stand which carries the projection lantern or the microprojection outfit. With this in use one may sit at a table in a darkened room and trace the projection of microscopic preparations, lantern-slides or of photographic negatives. A glance at the diagram will show the extreme simplicity of the parts involved.

A, shown also in end-section at A', is a piece of wood two by two inches and about three feet long, grooved by means of a rabbet plane so as to clamp firmly to the lantern table (see A'). The arm B bears the two grooved strips C which carry at an angle of 45° the mirror D. This casts the image on the drawing surface E, where it may be traced with ease.

The magnification depends directly upon the distance of the drawing board from the mirror. Thus if the enlargement is two times when line E-D is ten inches, the image will be enlarged four times if line E-D is twenty inches.

Magnification also depends, of course, upon the distance of mirror from the lens.

The apparatus has been especially helpful in making rapidly, and to scale, accurate drawings of insect wings, mouth-parts and the like. One student, who was also working in vertebrate zoology, found it of the greatest service in making from negatives enlarged drawings of the arrangement and distribution of the scales of various reptiles. But in addition to this outline work it is also perfectly feasible to use it with more detailed drawings from microscopic preparations if the room be well darkened. It is quite possible that a similar device has long been in use by others, but I have failed to find any mention of it and I have, therefore, thought that this description might be of aid to some.

WM. A. RILEY

SOCIETIES AND ACADEMIES

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 655th meeting was held November 21, 1908, President Bauer in the chair. Three papers were read at this meeting, as follows:

The Radiation Laws of Metals: W. W. CORLENTZ.

A knowledge of the laws governing the radiation of metals with variation in temperature is of interest in connection with the numerous speculations offered to explain the great light emissivity, i. e., the high luminous efficiency of the new incandescent lamps with metal filaments.

The speaker described some results obtained in an investigation of the most important so-called constant, α , of the type which obtains for a "black body" in which $\alpha - 1 = 4$, in Stefan's law of total radiation. The substances examined were tungsten, tantalum, osmium, platinum and several types of carbon filaments, usually in the form of 110-volt incandescent lamps. The spectral distribution of energy was measured with a bolometer.

It was found that the so-called constant, α , decreased with rise in temperature, and in all cases higher in value than that of platinum.

It seems to be a physical property of metals to have a low reflecting power in the visible, and especially in the ultra-violet, part of the spectrum. Throughout the infra-red the reflecting power of metals is uniformly high. The low reflecting power in the visible spectrum causes an abnormally high emission in this region, which, in con-

nection with the high values of the so-called constant, α , accounts for the high luminous efficiency.

Although it seems to have been overlooked heretofore, it is obvious that the so-called constant, α , must decrease in value and approach that of a "black body," otherwise a point would be attainable at which the radiation is greater than that of a black body at the same temperature.

From the results obtained it is evident that the spectral emissivity function of metals must be far more complex than that given in the Wien equation. Since the emissivity is a function of the reflecting power, which is a function of the refractive index and of the absorptive coefficient, which, in turn, are functions of the temperature, the wave-length and the electrical conductivity, it is evident that the spectral emissivity equations must contain factors which will take account of these phenomena.

Determination of Flexure of Pendulum Supports by the Interferometer: W. H. BUBBER.

In measuring the force of gravity by means of a swinging pendulum, the observations are necessarily made under varying conditions, and the period of vibration of the pendulum is consequently affected by many causes, and corrections have to be applied before the value of g can be ascertained. One of the important corrections results from the elastic yielding of the pendulum support. Several methods have been used to measure the flexure of the pendulum support and to ascertain its effect upon the period of the oscillating pendulum. Each of these methods contains some doubtful assumptions, and to avoid which the new plan of employing the interferometer for measuring the absolute displacement due to flexure of pendulum support was devised by Messrs. Hayford and Fischer, of the Coast and Geodetic Survey. The instrument used is a modified form of the Michelson interferometer. In observing, the instrument is separated into two parts, the main body of the instrument, and the mirror attached to the pendulum case, each being carried on entirely separate supports.

The experiments carried out by the speaker included tests of flexure of both pendulum case and of the pier upon which the case was mounted. The displacements were found to be movements of rotation. For comparison the static force method was also used in the experiments. Measurements of displacement were made with the pendulum case mounted with various substances between the

foot plates and pier. The investigations with the interferometer are still in progress, but it was the speaker's belief that the results so far attained should show that a distinct advance will be made in gravity observations when the flexure is determined by means of the interferometer.

Construction of Scientific Instruments and Their Adjustment; F. E. WRIGHT.

The paper dealt with the importance to science of knowing the degree of accuracy of scientific results, and the influence which the construction of the instrument may exercise in scientific investigation.

Under the head of informal communications, W. J. Humphreys spoke of the possible magnetic effect on the earth of wind storms, and of the recent discoveries made at Mt. Wilson regarding sun-spots.

R. L. FARIS,
Secretary

THE NEW YORK ACADEMY OF SCIENCES. SECTION OF ASTRONOMY, PHYSICS AND CHEMISTRY

At a meeting held on November 16 at the American Museum of Natural History Professor D. W. Hering was nominated for chairman of the section and a vice-president of the society for the ensuing year. Professor Wm. Campbell was re-elected secretary. The following papers were then presented:

On the Electrolytic Refining of Iron: E. F. KERN.

The previous work on this subject was reviewed; first, electroplating iron upon the surface of engraved copper plates to obtain a hard facing; then the work of Burgess and Hambueschen, of Gee, of Neuburger and von Klobukow, of Skrabel, of Maximowitsch and of Cowper-Coles. The electrolytes which have been most generally used are neutral solutions of ferrous sulphate or ferrous chloride containing respectively the sulphates or chlorides of ammonium. Smoother deposits were obtained by the presence of magnesium sulphate in an electrolyte of ferrous ammonium sulphate; by stirring the electrolyte; at a temperature of 60-70° C. Oxidation retarded by addition of glycerine. Precipitation of basic salts prevented by adding just sufficient acid to clear the solution. The iron deposited was a hard, brittle, crystalline mass, over 99.9 per cent. pure.

From experiments carried on in the department of metallurgy, Columbia University, it was found that neutral ferrous fluosilicate electrolytes are not suitable, as they are slowly decomposed with the separation out of silica.

Good deposits were obtained from neutral electrolytes containing either 8 per cent. iron, as FeSO_4 , or 6 per cent. iron and 3 per cent. sodium, as sulphates, or 8 per cent. iron and 4 per cent. sodium, as chlorides. With a current density of 10 to 20 amperes per square foot and a temperature of 50° C., the electromotive force for the first solution was 0.8 to 0.95 volt, for the second 0.5 to 0.85 volt, for the third 0.4 to 0.5 volt. The paper concluded with a discussion of the costs of electrolytic refining of iron.

W. Campbell read a paper on the "Use of Metallography in Certain Problems in Concentration." The unsuccessful attempts to concentrate the nickel in nickeliferous pyrrhotites were probably due to the fine condition of the pentlandite. Slides illustrating the structure of ores from different localities were shown. The structure of certain magnetic lead ores from Idaho was seen to be a fine-grained complex containing magnetite, quartz, calcite and other gangue, blende and galena, which were deposited in about that order. Magnetic separators applied to the zinc-lead middlings from the jigs yielded a lead-rich concentrate which was taken out by the magnets. The structure of a zinc ore at ground-water level, from New Mexico, was shown to be mainly rosettes and compact masses of specular hematite with zinc blende in the interstitial spaces. The following order was indicated: pyrite, hematite, chalcopyrite, blende and a little gangue. The difficulty in concentrating the zinc was due in part to structure.

W. Campbell read some notes on a "Visit to the Collieries and Iron and Steel Plants of Nova Scotia," illustrated by numerous lantern slides. The visit was made with the Canadian Mining Institute during the summer. The collieries of the Dominion Coal Company at Glace Bay were first seen, then the plant of the Dominion Iron and Steel Company. Piers with mechanical unloaders for ore from Newfoundland; four blast furnaces; ore beds for winter stock, blowing engines, etc.; two Bessemer converters, ten open-hearth furnaces; rail mill, rod mill; coke ovens and coal-washing plant. At North Sydney the Nova Scotia Steel and Coal Company has coal and ore piers, with two steam Wellman Seaver Morgan ore unloading cranes. Wabana ore from Bell Island, Newfoundland, averages 55 per cent. Fe. At Sydney mines the various collieries were visited. Here are coke ovens and coal washer, one blast furnace (200 tons a day), three forty-ton basic open-hearth furnaces and one rolling furnace of

180 tons used as mixer. Ingots are sent to the rolling mills at New Glasgow.

WILLIAM CAMPBELL,
Secretary

COLUMBIA UNIVERSITY,
NEW YORK

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND
MEDICINE

THE thirtieth meeting of the society was held at the College of Physicians and Surgeons, October 21, 1908, with President Lee in the chair.

Members present: Alsberg, Atkinson, Auer, Banzhaf, Burton-Opitz, Crile, Dakin, Ewing, Famulener, Flexner, Gies, Harris, Jobling, Joseph, Kast, Lee, Levene, Levin, Lusk, Mandel (A. R.), Meltzer, Meyer, Morgan, Noguchi, Opie, Park, Pearce, Shaffer, Terry, Van Slyke, Weil, Wells, Wolf.

Members elected: C. C. Guthrie, E. P. Lyon and Mazyck P. Ravenel.

Scientific Program

"Studies on the Chemistry of Anaphylaxis," H. Gideon Wells.

"Further Observations on the Clinical Aspects of Hemolysis," George W. Crile.

"The Behavior of Alanin in Metabolism," A. I. Ringer and Graham Lusk.

"An Important Source of Error in Heller's Test for Urinary Protein," William Weinberger (by invitation).

"A Clamp for Direct Transfusion of Blood" (a demonstration), Isaac Levin.

"The Further Separation of Antitoxin from its Associated Protein in Horse Serum," Edwin J. Banzhaf.

"Multiple Tumors in Mice," J. W. Jobling.

"On Plastein," D. D. Van Slyke and P. A. Levene.

"The Action of Bile and Some of its Constituents upon Intestinal Peristalsis and the Circulation," Isaac Ott and John C. Scott.

"The Uric Acid Excretion of Normal Men," Paul J. Hanzlik and Philip B. Hawk.

"Hemolysins in the Sera of Carcinoma and Syphilis," S. Peskind (by invitation).

'Authors' abstracts of the papers read before the Society for Experimental Biology and Medicine are published in the *Proceedings of the Society for Experimental Biology and Medicine*. A number is issued shortly after each meeting, and costs twenty cents a copy. Copies may be obtained from the managing editor, William J. Gies, 437 West 59th Street, New York.

"The Effect of Instilling Adrenalin Chloride into the Mammalian Eye," W. H. Schultz (by invitation).

"Successful Canine Infection with Cultures of *Leishmania infantum* (Ch. Nicolle)," Frederick G. Novy.

"New Apparatus for Use in Metabolism Work" (a demonstration), William J. Gies.

WILLIAM J. GIES,
Secretary

THE BIOLOGICAL SECTION OF THE ACADEMY OF
SCIENCE AND ART OF PITTSBURGH

AT a regular meeting of the section on December 1, Mr Richard R. Hice, of Beaver, Pa., spoke on the "Preglacial Drainage of Western Pennsylvania." Mr. Hice gave a concise summary of the work of Carll, White, Foshay, Jilison, Leverett, Campbell and Hice on the drainage of this part of the state. As outlined by him, the history of the region has been as follows: In the late Tertiary there existed a fairly well-developed river system draining northward into the Erie basin through the upper Ohio and Beaver valleys. This system was destroyed by the advance of the Kansan ice, which dammed the rivers, forming Lake Monongahela. The water was thus raised to such a height that it spilled over the divide below Wheeling, and the formation of the present Ohio was begun. A period of uplift followed, during which the rivers draining toward the southwest cut their channels far below the present level of the river bottoms. During the later part of the Wisconsin ice-advance and following the retreat of the ice, there was a settling of the land and the valleys were filled to a point above the present stream level with glacial debris. At the present time the streams are engaged in lowering their beds in these sands and gravels.

PERCY E. RAYMOND,
Secretary

THE ELISHA MITCHELL SCIENTIFIC SOCIETY OF THE
UNIVERSITY OF NORTH CAROLINA

THE 180th meeting of the society was held in Chemistry Hall on Tuesday, November 10, 1908, 7:30 P.M. The program was as follows:

"A Trip to Europe for Geographical Study" (illustrated with lantern slides), Professor Collier Cobb.

"A Rapid Method for Determination of Oil in Cotton-seed Products," Professor Chas. H. Herty.

ALVIN S. WHEELER,
Recording Secretary

THE BALTIMORE MEETING

The Baltimore meeting of the American Association for the Advancement of Science and the affiliated national scientific societies has never been equalled in size and importance by any gathering of scientific men in this country or indeed elsewhere. It might have been expected that the meetings held in the great centers of population last year and the year before would have set the high water mark of attendance for some years, but the registration at Baltimore was even larger than at New York or Chicago, and the percentage not registering was greater than ever before. Registration can only be regarded as a habit or duty, as it confers no privilege, the list not even being printed. Of the 300 chemists at the New York meeting only 106 registered; at Baltimore, where the chemists met in a distant part of the city with an attendance of about 400, perhaps not more than 50 registered. The actual registration of members of the association was 1088; the attendance at the meeting can only be guessed, but it may have been in excess of 2,500.

Size is not in itself significant; it may be an advantage or it may be a nuisance. But in so far as the growth of the convocation week meetings means an increased number of scientific workers in this country and a willingness on their part to cooperate, it is grati-

fyng and important. A very large meeting has for those in attendance certain advantages and certain disadvantages. It is irritating not to be able to attend the conflicting meetings of nearly equal interest and not to be able to converse at leisure with friends and acquaintances. It should, however, be remembered that if the different societies were meeting in different cities, it would be still less possible to attend the meetings that one would like to attend and to see the friends that one would like to see. It might be possible for the sciences devoted to the biological sciences to meet in one city and for the sciences devoted to the physical sciences to meet elsewhere; perhaps for the geologists and the philosophers to meet by themselves. But in such a case what are the biological chemists, the biometricians, the students of evolution, the cosmical physicists, the geographers, the psychologists, etc., to do?

The real conflict is not between the chemists and the zoologists, for example, but within the single science. Thus at Baltimore the Zoological Society of America and the zoological section of the association each had some sixty papers on its program; there were two entomological societies and a society of vertebrate paleontologists in session, the psychologists had a morning devoted to animal intelligence, etc. It is not possible to read and discuss consecutively three hundred papers. The best that can be done is to have sessions of interest to all scientific men, to all biologists, to all zoologists, and then to divide zoology into sections for the reading and

discussion of special papers in different departments. The chemists, whose numbers are the largest, have naturally led the way in organization. They have well-organized sections throughout the country for frequent local meetings; they have a summer meeting, usually by themselves, and meet with the other societies in convocation week; they have certain general meetings and then divide into numerous sections; all the papers in chemistry are referred to the American Chemical Society which organizes the joint program.

We may look back with certain regrets to the "good old days" when there were so few workers in each science that they could all be acquainted with one another and with one another's work, or still further back to the age of academies when all the scientific men of a city or county could meet together with common interests; but no one imagines that we can go back to these days, or that it would be desirable to do so. It is like the man who has acquired wealth and power and thinks of past days when life was less complicated and perhaps happier.

Haply, the river of Time—
As it grows, as the towns on its marge
Fling their wavering lights
On a wider, statelier stream—
May acquire, if not the calm
Of its early mountainous shore,
Yet a solemn peace of its own.

It is of course true that the problems of scientific organization are by no means solved. Some of them may be settled in a satisfactory manner; others may be quite unsolvable. There were at the present meeting needless mistakes of the program,

such as announcing the wrong building for the address of the president and the wrong afternoon for the meeting of the Naturalists; needless dispersion, as in sending the sections of anthropology and of education to large auditoriums at a distance when the lecture rooms of the university would have held and secured larger audiences than were present; needless conflicts, as the programs of the Zoological Society and the Section of Zoology in adjacent rooms. There should be one man thoroughly familiar with the situation and competent to do the best that can be done under the circumstances. We need a secretary of science for the country, not less influential and not less well paid than the secretary of the Smithsonian Institution, who will devote his whole time to the organization of science and of scientific men.

It is quite possible that it would be better to have a convocation week meeting only on alternate years, or even less often, leaving the societies to scatter in intervening years. Or it might be better to divide the association into sections for the eastern, central and western states and hold a joint meeting once in three or in five years. Again it might be well to have an association devoted to the diffusion and popularization of science, separate from an affiliation of the scientific societies composed of professional scientific men. At present the association fails chiefly in the former function. It has a considerable membership in addition to the scientific workers of the country, and there were many sessions at Baltimore that would have been

interesting and useful to them, but practically none were present. The association also fails to exert an influence on the general public through the press.

But in spite of difficulties and partial failures, the convocation week meetings have since their establishment in Washington six years ago performed a great service for science and for scientific men. They lead men of science to recognize the community of interest that should obtain; they impress on the general public the weight and magnitude of science; the council, representing the scientific interests of the country, may become an important factor in their advancement. The members of the association, all of whom have the privilege, or at least the opportunity, of reading this journal, have increased from 1,721 in 1899 to over 7,500. All this represents a coordination that may be used effectively for the advancement of science; and whatever forwards the advancement of science is for the benefit of every one.

An account of the business transacted by the council representing the association and the affiliated societies will be given in the report of the general secretary, and this will be followed by accounts of the proceedings of the several sections and of the different societies and by some of the more important addresses, papers and discussions.

The association was fortunate in being welcomed to the Johns Hopkins University and to Baltimore by two of its distinguished recent presidents, and in having as president of the meeting one of the world's most eminent geologists whose

public services extend far beyond the bounds of his science. The admirable address of the retiring president, printed last week in *SCIENCE*, deserves to be read by every intelligent citizen. It is unfortunate that our daily papers will not follow the example set in Great Britain and print in full an address of this character. Several of the vice-presidential addresses before the sections of the association and several of the presidential addresses before the special societies were of great general interest, while others equally important were technical in character. It would perhaps be desirable if the vice-presidential addresses were always addressed to an intelligent audience rather than to specialists, or at all events if the program would indicate the class for whom each is intended. Among the interesting public lectures may be noted the following: Professor Poulton, of Oxford, on "Mimicry in the butterflies of North America"; Professor Penck, of Berlin, on "Man, climate and soil"; Professor Münsterberg, of Harvard, on "The problem of beauty"; Mr. Bryan, of Honolulu, on "A visit to Mount Kilauea"; Major Squier, U.S.A., on "Recent progress in aeronautics," and Mr. G. K. Gilbert, of the U. S. Geological Survey, on "Earthquake forecasts."

It seems to be scarcely credible, but it is the case, that there were on the program published by the association the titles of more than one thousand papers to be read at the meeting. The great majority of the papers represent research work of a high order. It is sometimes said that the

United States is not doing its part in the advancement of science, but this program is a conclusive answer to such criticism. No other country except Germany could hold a meeting in which so many scientific researches maintaining such high standards could be presented as the result of a year's work, and Germany has never held such a meeting.

These papers were in the main special and technical in character, but there were in each science papers containing results of interest to a wide group of scientific men, and in many cases papers and discussions of broad interest to the general public. Among these were the series of addresses before the American Chemical Society, the symposium on correlation in which sixteen leading geologists took part, three general discussions arranged by the botanists, the symposia on college education and life, on physical instruction in schools and colleges, and on public health. Most important of all—perhaps the most significant scientific celebration hitherto held in this country—was the Darwin centenary memorial. Professor E. B. Poulton, the leading exponent of natural selection, came from England to take part, and after his address a series of papers was presented by our leading workers in problems bearing on evolution. The day's proceedings closed with a dinner, at which speeches were made by President Chamberlin, Professor Osborn, Professor Welch, Professor Penck and Professor Poulton.

The meeting next year will be held at Boston under the presidency of Dr. David

Starr Jordan, president of Stanford University. It was recommended that the following meeting be held in Minneapolis. All the affiliated societies will probably wish to go to Boston, and the meeting is likely to surpass in importance even the present meeting. In the following year the special societies whose membership is chiefly on the Atlantic seaboard will have an opportunity to meet separately. In order that the societies may have information in planning joint or separate meetings, the general committee voted that it looked with favor on convocation week meetings in Washington, Cleveland and Toronto, following those in Boston and Minneapolis. The council of the British Association has invited members of the association to attend the Winnipeg meeting next August, the officers as honorary members. In the following summer a meeting will probably be held in Honolulu.

SCIENCE TEACHING AS A CAREER¹

It is scarcely a serious exaggeration to say that the first thought regarding a teacher which comes to the minds of many estimable people is that of a person who, by virtue of a greater or less assumption of knowledge, is able to occupy a position in which he has frequent long vacations, and in the interim draws a comfortable salary for comparatively short working hours. Such, at least, is the conclusion which may apparently be drawn from the frequency with which these topics are introduced into conversations incident especially to the

making of new acquaintances. But these same persons would many times experience a tinge of regret if their sons should choose to adopt this career, and that not because they definitely believe it to be an unworthy or inadequate career, but because they understand very little about it. It is, however, not only true that this supposedly comfortable profession is not overcrowded, but there is evidence that there is a positive dearth of able young men who have both the aptitude and disposition to become teachers. It seems to me, therefore, fitting that we who are interested in the advancement of science should spend a few minutes in the consideration of the conditions which confront a young man who is disposed to become a teacher of science, since the maintenance of a corps of competent teachers is of no less interest to us all, practitioners as well as pedagogues, than are the subjects which they should teach, some of which have been ably discussed in recent addresses.

It is the more appropriate that this question should be considered at this time, since certain presumably authoritative data regarding the compensation of teachers have recently become available, and because the establishment of a section on Chemical Education on the part of the American Chemical Society, the first session of which follows this address, indicates an awakening interest in all that pertains to the education of the chemist and chemical engineer, among which the question of the best means to maintain our supply of capable teachers must assume an important place.

What I shall say will apply doubtless most closely to teachers of chemical science in institutions of college grade, because the conditions under which they labor are most familiar to me; but much that may be said of these teachers is true of those in other sciences which stand in a relation to the arts similar to that of chemistry. A

¹ Address delivered by the retiring chairman of Section C of the American Association for the Advancement of Science, at Baltimore, December, 1908.

great deal has been written on this and similar topics, and I can claim very little originality in the thoughts which follow. I present them in the hope that they may arouse in you, parents, employers, practitioners and teachers, an increased interest in the general welfare of those to whom the teaching of science is entrusted.

It may first be asked, What ground exists for the assumption that there is a present or prospective lack of science teachers? It seems to me that this is indicated by the increasing difficulty which is reported from various institutions and from various departments as having been experienced in filling their instructing corps with the best type of men. I know this to be true in chemistry from my own experience, and from the marked increase in the number of applications for assistants which have come to me from all parts of the country. Unless many of us misjudge the trend of the times, the increasing pressure of competition, making necessary the improvement of old and the devising of new means for the utilization of by-products and waste materials, the greater refinement of products without added cost, demanded by the consumer, and the awakening of the country to the necessity of husbanding its natural resources, all tend to place the chemist and chemical engineer in the forefront of industrial activity, and to make those professions increasingly attractive to our young men, as affording unexcelled opportunities for productive work in a field which at present is not overcrowded. If, at the same time, it is possible by missionary effort to dispel the well-established notion among fond parents that chemistry, pure or applied, is synonymous with explosions and impaired health—an opinion which lacks a statistical basis—the number of young men entering the profession will doubtless increase, but it may fairly be questioned whether what

may be designated as the “call of the practical” will not prove increasingly alluring, and our difficulties in retaining able men of the type which we desire to enlist in the service of our institutions, become more and more serious.

Let us face this situation squarely and ask, What is it that makes this “call of the practical” so enticing to ambitious, thoughtful young men who are conscious of their ability to get results, or, perhaps, merely hopeful of a fair measure of success in what they undertake? Money and opportunity are obviously the influential factors; and in the best type of men the latter is likely to be given the greater weight in the selection of a life work. Let us look at these a bit more closely. No one acquainted with existing conditions, if appealed to for advice by a young man facing his choice of a career, would fail to point out to him the probable financial sacrifice involved in the selection of the work of a teacher. Indeed, this is so serious a question that in the case of a young man who may be without financial resources other than his earnings, but is tactful in his dealings with his fellowmen, of high scholarship, and with ability to think independently—just the man who is needed in our corps of teachers—one may well pause before uttering decisive words of counsel which will almost certainly be of great influence in determining the material prosperity of his later life; of greater influence, I sometimes fear, than our knowledge of the past or our prescience really warrants.

How great, in reality, is the financial sacrifice involved in a decision to enter the teaching profession? Data regarding the compensation of teachers in institutions of college grade have recently been made public by the Carnegie Foundation for the Advancement of Teaching in its Bulletin Number Two, on “The Financial Status of

the Professor in America and Germany." In view of the unusual opportunity possessed by the Foundation for the gathering of authoritative data, the figures presented merit attention. No distinctions are made between teachers of science and those in other departments, but, considering salaries only, it does not appear that marked differences exist, and it is probable that the average salaries as there given may be taken as being also representative of those of science teachers. Some of the more relevant statements are as follows: Considering one hundred and three institutions in the United States and Canada which have an annual salary budget of \$45,000 and over, the average salary of a full professorship ranges from \$1,350 to \$4,788. Only eight institutions report an average below \$1,800, and only nine an average above \$3,500. Half of these institutions average less than \$2,200. Taking them all into account, the average appears to be close to \$2,500, but there are more below than above this figure. Individual salaries apparently vary from about \$500 to \$8,000, both being, however, exceptional.

The average salary of an assistant professor is about \$1,600 (half of the institutions pay less than \$1,500); and the salary for the grade of instructor averages a little over \$1,000.

Closely linked with the amount of the salaries paid is the question of the period in the teacher's life when the various amounts may be expected to be obtainable. On this point the statement in the bulletin, based on the available data, is this:

A man acceptable to these institutions for a position worth \$1,250 will be on an average 28 years old; a man appointed to a position worth \$1,750 will be on an average 31 years old when appointed to it; one appointed to a position worth \$2,250 will be on an average 33 years old; one appointed to a position worth \$2,500 or over will be on an average 34 years old.

And elsewhere it is stated that appointments to positions carrying salaries of \$3,000 and upward are not usually made before at least 35 to 39 years of life have been completed.

It is interesting to note in passing that the data from fifty-four additional institutions having salary budgets below \$45,000 annually, indicate that the average salary of a full professorship in them is \$1,800, and that this is reached by men when about 33 years of age.

The average salary of an assistant approximates \$500. It is, however, properly emphasized that the period of service as assistant is essentially one of apprenticeship, during which the incumbent gains much more than is represented by the monthly salary check. Indeed, it is my own conviction that a year of service of this character is, to a right-minded young man, nearly the equivalent of a year of post-graduate study, and affords an experience which is valuable, whether the career ultimately chosen is that of a teacher, or lies in the commercial field.

In order to determine whether, or by approximately how much, the teacher is at a disadvantage as compared with others of equal age and training in other occupations, information was collected by the Carnegie Foundation which is to the effect that the average competent lawyer and competent engineer, after being out of the professional school about eight or ten years (thus approximating the age at which a full professorship with an average salary of \$2,500 is attained) would be earning in New York between four and five thousand dollars a year. A physician might earn somewhat more. The average professor's salary at Columbia University is \$4,289, while that of the College of the City of New York is \$4,788; but, for special reasons, these averages are said to be abnormal. The corresponding figure for Stevens Institute

of Technology is \$3,200, and that for Brooklyn Polytechnic Institute is \$2,783. It appears, then, that the average college professor at 34 is receiving a less return than his contemporary in other professions by perhaps \$1,000 per year, although there may well be individual instances in which there is little disparity. But this is not the main issue; for, as is pointed out in the bulletin referred to, it is at this point that the divergence in the financial rewards begins to increase rapidly. The salary of the full professorship, reached at 34, represents nearly the limit of the earning power of the incumbent if, as is so often true in our institutions, his entire energies are consumed in his institutional service, unless perchance he occupies some position carrying with it special administrative responsibilities. His colleague without the walls of the college has, on the other hand, also just entered upon his most productive period, and may reasonably hope to see his income increase into the tens of thousands, permitting him to maintain a comfortable home and affording him means to meet the growing expenses incident to the education of his children. So far, then, as young men are influenced by the maximum financial rewards and prizes attainable, it must frankly be admitted that, at present, the teaching profession is at a disadvantage.

But I am personally disposed to believe that such difficulties as exist in securing and holding able men as teachers of science are less the result of the comparatively small maximum returns which may be expected when the final stage in professional promotion has been reached, than because of the depressing conditions which confront them during the long period which now elapses between the attainment of salaries of \$800 to \$1,000, and a salary of \$2,000, a period which, in the larger institutions is probably rather more than six

years. The young teacher's apprenticeship as assistant or junior instructor is over, and he is anxious to feel that his long period of study and development is bringing him an adequate return, and he hears his classmates tell of bridges built, factories started, laurels won, and salaries raised—sometimes with an all-too-thinly veiled suggestion that he has chosen the less worthy rôle—and he longs to join those who can boast of material successes. To this is often added the proper desire for a home of his own. Or perhaps the home has been established, when there must be a struggle to provide those comforts (not luxuries in an extravagant sense), which his temperament and training lead him to desire, which his institution and his community tacitly expect of him, and which above all, would make of him a man of growing refinement such as we are increasingly in need of in our teaching ranks. Helpful and necessary as it is to increase the salaries of the higher paid professional positions as soon as this is possible, I believe that there is a still more urgent need that the salaries of the junior grades should be earlier lifted to a point at which the strain of anxiety is removed and moderate comfort and congenial surroundings are made possible. This is, of course, mainly true of our larger institutions, or those situated in communities where the cost of living is now so sadly out of proportion to the amounts on the salary lists, but it may be questioned whether the ratio of income to outgo is essentially better in smaller institutions and places. I believe that this is a matter which all of the college authorities should consider in order that this period may prove less repellent and that the rounding out of the non-professional side of the science teacher, which is often so large a factor in his success, may not be postponed until many of his best years have been spent in a de-

pressing effort to accomplish the impossible. A young teacher is fortunate if, during this time, he is not obliged to suppress his desire for research, acquired by years of training, in order to avail himself of opportunities to add something to his meager income.

Data concerning the salaries paid to teachers of science in public schools below college grade are to be found in the Report of the Committee of the National Educational Association on Salaries, Tenure and Pensions of Public School Teachers in the United States, dated July, 1905. From the extensive tables there given it would appear that the average maximum salary paid to male teachers in cities or towns having from 8,000 to 12,000 inhabitants is about \$800 per year, in cities numbering 10,000 to 15,000 about \$1,000, in those of 15,000 to 30,000 population about \$1,200, in cities of 30,000 to 75,000 inhabitants about \$1,500, and so on up to cities of 200,000 inhabitants or over, when the maximum is about \$2,000. The highest salaries are paid in New York, amounting probably to \$3,500 for those having positions of sub-masters or heads of departments. The opinion has been expressed to me by well-informed science teachers that the salaries paid such teachers do not differ essentially from the average salaries named above, but that salaries paid by private schools may be in general somewhat higher than the figures named. Here, again, it seems to me that those in authority should realize that more than a bare living wage must be provided for the younger teachers if the best results are to be obtained, and my own observations lead me to express a further belief that the efficiency of these teachers is much less than it might well be because of inadequate assistance—a condition of affairs which makes it necessary for them to devote time which should be spent in instruction to the mere distribution of supplies. It is

expected that these and other related topics will be considered in detail at some early session of the Education Section of the American Chemical Society. I will not, therefore, dwell longer upon them now.

It has already been said that the opportunity for accomplishment which the technical field opens before the young man is alluring to a high degree, and, although I have thought it wise to dwell first upon the financial aspects of a teacher's career, I am far from thinking that the avoidance or abandonment of that career by those who have shown themselves fitted to enter upon it, is mainly due to anything which could be described as greed or avarice. What, indeed, can be better worth undertaking than the development of a new industrial process, very likely the product of one's own careful thought; to watch it grow from a thing of the beaker and test-tube in the laboratory to the successful operating plant, where tons are substituted for grams? Where are there problems better worth attacking than the careful investigation of sources of difficulty in existing processes, with the sense of satisfaction and triumph which accompanies their ultimate rejuvenation? And to whom does there come wider opportunity for honorable service and tangible reward than to one who, through leadership and the helpful guidance of a corps of trained investigators such as are found in the research laboratories of some of our larger manufacturing organizations, has at once the privilege of extending the boundaries of his chosen science and, by improving or cheapening production, to increase industrial efficiency, which in many instances means ultimate benefit for us all. The joy of material accomplishment belongs to the worker in each of these fields.

What is there, then, left to be said in behalf of science teaching as a career? Very much; almost everything indeed, if

we are speaking to the man whose aptitude lies in that field. Let us turn again for a moment to its bug-bear, the financial side, which will then be finally dismissed. Conditions are not just as we, the teachers, or the college authorities, would desire them to be, but there are signs of improvement, which this Association and the Chemical Society can promote. But after all, the teacher's patience is ultimately rewarded by a monetary return which for the really able man (who alone would receive the higher rewards in the commercial field) is not inconsiderable. Moreover, his tenure of office is in general secure during good behavior, and it is no small comfort to feel that the salary check, though of moderate amount, will appear regularly during those times of stress when our supposedly more fortunate brothers are growing grey with anxiety regarding the next turn of the market.

The science teacher of to-day is, moreover, usually something of a specialist and expert, and I believe that it is his duty, as well as his privilege, to make himself acquainted with the applications of his specialized knowledge in the technical field, and so far as it may be done without violence to duties already assumed, to avail himself of opportunities for expert service, especially where these involve an impartial treatment of problems of some importance. Service of this sort well-performed is highly remunerative, and serves at once to broaden the teacher and to contribute to the comfort of those dependent upon him; and in individual instances, to relieve much of the disparity between the income of the teacher and the technician. In this respect the science teacher possesses a distinct advantage over his brother in the academic field, and the engineer or chemist an advantage over the specialist in a descriptive science, such as astronomy.

The effect of the establishment of the Carnegie Foundation for the Advancement of Teaching must not be overlooked. Its generous endowment provides, as many of you know, retiring pensions which may be claimed as of right by teachers who have served in a professorial capacity for twenty-five years, or who have reached the age of sixty-five, with a record of fifteen years of professorial work. Provision is also made for the family of a teacher who at the time of his death was entitled to a pension. It may, however, be noted that at present no general provision is made for the same class of junior professors referred to above as struggling with meager salaries. It would undoubtedly prove exceedingly helpful, both by relieving anxiety and by making the teaching profession more attractive, if it were ultimately found practicable to provide widows' pensions in the case of the death of junior teachers who have not completed the prescribed twenty-five years of service. It is apparently true, however, that the trustees of the Foundation would even now consider individual cases of need, on their merits.

But what of the opportunities, the privileges of the teacher? They are almost limitless. Is there drudgery? Yes; but what vocation is without it? Does he have to repeat the same story year after year? In part, yes; but it never need be wholly the same and the audience is never twice the same. And the long vacations? They are available, if they are needed (and then they are blessed indeed), but they are seldom periods of continuous idleness, but are rather one of the great opportunities which come to the teacher, as to few others who are under obligations to render definite services. To the progressive, enthusiastic teacher these should be periods of growth; a chance for uninterrupted thought regarding his specialty or his work; a chance

notes and hoped to bring them out in a separate publication.

Giard stayed in Lille until 1887, when he accepted a call to Paris as professor in the École Normale Supérieure, and a year later the municipality created for him a professorship in the Sorbonne for the *Évolution des Êtres organisés*, which he occupied up to the time of his death.

In 1900 he was elected a member of the Academy of Sciences, and during the last few years several of the most important foreign academies had likewise admitted him to their ranks.

There was scarcely a contemporary naturalist who possessed in similar degree Giard's gift of interesting and attracting younger workers. His manner was cordial, happy, inspiring; his students felt that they could rely upon him, and he in turn guided their steps with the keenest interest, gave them his personal support in their career and rejoiced with them in their success. He was not only a master but a true and wise friend.

His science was eminently altruistic; he worked surrounded by his pupils, happy to see them continue and complete discoveries which he had already outlined. His faculty of observation drew his attention to what might prove interesting in many branches. In almost every group he found material for study, and his works consisted chiefly of short papers, results of personal investigations, full of original and suggestive ideas. Nearly every aspect of biology was touched upon—systematic zoology, anatomy, embryology, etiology, comparative pathology, teratology, applied zoology, botany, zoological philosophy. His papers are dispersed among a multitude of periodicals, and it would be a difficult task to collect them had there not been published the usual complete bibliography and résumé (1896) when he was admitted to the Academy of Sciences.*

I will mention only a few of Giard's most important results: such, for example, are his numerous researches on parasitism, during

which he discovered many very curious types, *e. g.*, the orthonectida, also an admirable series of papers in collaboration with Jules Bonnier on the epicarides, the isopodous parasites of crustacea. His synthetic genius, combined with minute observation and rare erudition, enabled him to seize and combine ideas and facts which would otherwise seem to have no connection, and he introduced into general biology new and important ideas founded on well-proved experiences. For instance, the action of water and the phenomena of *anhydrobiosis*, the curious modifications produced by parasites on their hosts, *e. g.*, in cases of castration by parasites, and the interesting variations of development of individuals of the same species or closely approaching species which he called appropriately *pœcilogony*.

Giard was one of the few naturalists who had the gift of being both original and encyclopedic. He possessed in an unusual degree a knowledge of infinite details of nature and of general philosophy, as one can judge indeed from the lecture he delivered at St. Louis in 1904.⁴

His brilliant intellect and prodigious memory enabled him to retain the quantity of material contained in his wide-spread readings, so that he was really a living encyclopedia and always up to date, opening immediately at the page wanted, to be examined at leisure by all who desired to acquire knowledge.

All these qualities remained unobscured to the last day of his life, and his loss is felt as an untimely one to all who came in touch with his many activities.

It is as though a torch carried before the crowd to light the way had been too soon extinguished.

M. CAULLERY

UNIVERSITY OF PARIS

SCIENTIFIC NOTES AND NEWS

DR. DAVID STARR JORDAN, president of Stanford University, has been elected president of the American Association for the Advancement of Science for the meeting to be held

*"Les tendances actuelles de la morphologie et ses rapports avec les autres sciences."

*"Exposé des titres et travaux scientifiques (1869-96) d'Alfred Giard," Paris, 1896, in quarto, 306 pp.

next year in Boston. The vice-presidents for the sections and newly elected secretaries are as follows:

Section A—Mathematics and Astronomy—Professor Ernest W. Brown, Yale University.

Section B—Physics—Dr. L. A. Bauer, Carnegie Institution, Washington, D. C.

Section C—Chemistry—Professor William McPherson, Ohio State University.

Section D—Mechanical Science and Engineering—Dr. J. F. Hayford, U. S. Coast and Geodetic Survey.

Section E—Geology and Geography—Dr. R. W. Brock, director of the Canadian Geological Survey.

Section F—Zoology—Professor William E. Ritter, University of California.

Section G—Botany—Professor D. P. Penhallow, McGill University.

Section H—Anthropology and Psychology—Dr. William H. Holmes, Bureau of American Ethnology.

Section I—Social and Economic Science—President Carroll D. Wright, Clark College.

Section K—Physiology and Experimental Medicine—Professor Charles S. Minot, Harvard Medical School.

Section L—Education—Professor J. E. Russell, dean of Teachers College, Columbia University.

General Secretary—Professor Dayton C. Miller, Case School of Applied Science.

Secretary of the Council—Dr. F. G. Benedict, director of the Nutrition Laboratory of the Carnegie Institution.

Secretary of Section H—Anthropology—Professor George Grant MacCurdy, Yale University.

Secretary of Section K—Physiology and Experimental Medicine—Dr. George T. Kemp, Champaign, Ill.

THE officers of the American Society of Naturalists elected at the Baltimore meeting are as follows: *President*, Professor T. H. Morgan, of Columbia University; *Vice-president for the Eastern Section*, Professor W. H. Howell, Johns Hopkins University; *additional members of the Council*, Dr. D. T. MacDougall and Professor Charles H. Judd. Professor H. McE. Knowler and Dr. Hermann von Schrenck were reelected as secretary and treasurer, respectively.

PRESIDING officers of societies meeting at Baltimore were elected as follows: The Geological Society of America, Mr. G. K. Gilbert,

of the U. S. Geological Survey, for the second time, he having held this office in 1892; The American Chemical Society, Dr. W. R. Whitney, director of the Research Laboratories of the General Electric Company, at Schenectady; The American Zoological Society, Professor Herbert E. Jennings, of the Johns Hopkins University; The American Anthropological Association, Dr. W. H. Holmes, chief of the Bureau of American Ethnology; The American Psychological Association, Professor Charles H. Judd, professor of psychology at Yale University and director-elect of the School of Education in the University of Chicago.

PROFESSOR T. C. CHAMBERLIN, after presiding at the Baltimore meeting of the American Association, left for San Francisco on his way to China, where he will study the geology of the country with special reference to its influence on social and educational conditions, as a member of a commission sent by the University of Chicago.

DR. ERNST HAECKEL, professor of zoology in the University of Jena, will retire from active service at the close of the present semester.

At the commemoration of the centenary of Charles Darwin by the University of Cambridge in June, 1909, the Royal Geographical Society will be represented by its president, Major Leonard Darwin.

PROFESSOR HERMANN VOLZ, the sculptor of the Bunsen monument at Heidelberg, has been given an honorary doctorate by the university.

SIR ARCHIBALD GEIKIE will give an address on the occasion of the celebration of the fiftieth anniversary of the Geological Society of Glasgow to be held on January 28.

DR. NORMAN E. DITMAN, instructor in pathology at Columbia University, has been appointed by President Butler chairman of a committee of twelve to investigate and report at an early date, upon the feasibility of establishing at Columbia a school or department of sanitation.

DR. J. J. KINYOUN has been appointed pathologist and Dr. Truman Abbe, radiologist

on the staff of the Tuberculosis Hospital at Washington.

DR. EDWARD C. HILL has been appointed chemist in charge of the state station of the United States Department of Agriculture recently opened in Denver.

A DINNER was given at Saranac Lake on December 19, at which Dr. Baldwin presented Dr. E. L. Trudeau with two volumes of reprints on the "Studies in Tuberculosis" by his pupils in commemoration of his sixtieth birthday. Dr. Walter V. James presented Dr. Trudeau with letters from personal friends congratulating him on the occasion.

WE learn from the *Journal* of the American Medical Association that the French government has conferred the decoration of the Legion of Honor on Dr. Carlos J. Finlay, of Havana, in appreciation of his discoveries in regard to the transmission of infection by mosquitoes. The presentation of the decoration was celebrated, at the same time as his seventy-fifth birthday, at a special meeting of local and national notables in the assembly hall of the Academy of Sciences, Havana. At the same time a decree of the provisional governor was read setting forth the importance to the Cuban people of the professional services of Dr. Finlay, especially in connection with the discovery of the means of transmitting yellow fever. This decree provides for the retirement of Dr. Finlay at his own request and because of his advanced age, from the position of chief sanitary officer, and for his appointment as honorary president of the National Board of Sanitation and Charities, which office is created for his life time and will terminate with his death. The salary of this position is to be \$2,500 per year. The decree also provides for the publication by the government of a volume of selections from the writings of Dr. Finlay, not to exceed 500 pages nor 1,000 copies.

THE Board for Biology and Geology at Cambridge University has adjudged the Walsingham medal for 1908 to C. C. Dobell, B.A., fellow of Trinity College, for his essays entitled "Protista parasitic in frogs and toads," and "Chromidia and the binuclearity

hypotheses"; and a second Walsingham medal to G. R. Mines, B.A., Sidney Sussex College, and D. Thoday, B.A., Trinity College. Mr. Mines's essay was entitled, "The spontaneous movements of amphibian muscles in saline solutions"; and Mr. Thoday's essay was entitled, "Increase of dry weight as a measure of assimilation."

PROFESSOR FREDERICK STARR, of the department of anthropology of the University of Chicago, gave, on December 9, a lecture at the Ohio State University on "The Peoples of the Congo Free State." This lecture was the first to be given by the Society of Sigma Xi under the J. C. Campbell Lecture Fund.

GEORGE WASHINGTON HOUGH, professor of astronomy at Northwestern University and director of the Dearborn Observatory, known for his important observations on Jupiter and for measurements of double stars, vice-president of the American Association for the Advancement of Science in 1902, died at Chicago on January 1 at the age of seventy-three years.

DR. J. P. GORDY, professor of the history of education in New York University, and his wife committed suicide on December 31, following the death of their only child. Dr. Gordy was born in Salisbury, Md., 1852, received the doctor's degree at Leipzig in 1884, and was professor at Ohio University and Ohio State University until he came to New York University in 1901. He was the author of works on psychology, American history and the history of education.

DR. RICHARD A. F. PENROSE, formerly professor in the University of Pennsylvania, and eminent as a physician and surgeon, died in Philadelphia on December 26, at the age of eighty-two years.

MR. JOSEPH LOMAS, lecturer in geology in Liverpool University, has been killed by a railway accident in Algeria, where he was carrying on geological investigations.

DR. CHARLES EDWARD BEEVOR, known for his contributions to the knowledge of our nervous system, died in London on December 5 at the age of fifty-four years.

DR. ERNEST HAMY, professor of anthropology in the Natural History Museum, Paris, died on November 18, at the age of sixty-six years.

LORD ROSSE bequeathed £1,000 to Trinity College, Dublin, for the science schools. His telescope and scientific instruments are left to his oldest son, with £2,000 for their upkeep.

A CORRESPONDENT writes to the *London Times* that the Nizam of Haidarabad has established a well-equipped astronomical observatory in his dominions. The foundation of the observatory owes its origin, to the presentation by the late Haidarabad noble, Nawab Zaffer Jung Bahadur, F.R.A.S., of two large telescopes, but it is evident from the equipment of the observatory, from the selection of its director, and from the working program which has been drawn up, that his Highness intends to go far beyond the original intention of the donor, Nawab Zaffer Jung. The equipment includes, besides the purely astronomical and meteorological instruments, a very complete photographic department and extensive workshops fitted with modern tools and appliances for both wood and metal working. The program of the observatory is both comprehensive and ambitious.

By the President's order the Secretary of the Interior has withdrawn from entry all the public lands, embracing about 6,500 acres in the petroleum and natural gas field in northwestern Louisiana known as the Caddo oil field. This action is taken pending a careful geologic investigation by the U. S. Geological Survey with a view to preventing a waste of natural gas that has been estimated at 75,000,000 cubic feet a day, or more than one twentieth of the amount of this fuel usefully consumed in the United States.

PRESIDENT ROOSEVELT has signed a proclamation setting aside and naming the Ocala National Forest in Marion County, in eastern Florida, the first created east of the Mississippi River, and another proclamation creating the Dakota National Forest in Billings County, North Dakota. The two proclamations add two more states to the list of those wherein land will be put under scientific forest admin-

istration. There are now nineteen states, and Alaska, having national forests. Before the creation of the Ocala, in Florida, the two forests in Arkansas, the Ozark and the Arkansas, were the easternmost national forests. Practically all the other national forests are in the Rocky Mountain and the Pacific coast states. The Florida forest has an area of 201,480 acres, of which about one fourth has been taken up under various land laws. It covers a plateau between the St. John's and Ochlawaha rivers and at no point is an elevation exceeding 150 feet above sea level obtained. The area is by nature better fitted for the production of forest growth than for any other purpose. Nearly all of the area, however, seems particularly well adapted to the growth of sand pine which is even now replacing the less valuable species, and with protection from fire almost the entire area will in time undoubtedly be covered with a dense stand of this species. The long-leaf pine, a much more valuable commercial tree than the sand pine, appears rather sparsely in this forest and is confined principally to the lower flat lands along the streams on the borders of the forest. The new Dakota national forest consists of 14,080 acres in the Bad Lands region. Its creation is important, for it means that an experimental field for forest planting has been secured in North Dakota, the least forested state in the union, having only one per cent. of tree growth. The Forest Service expects to establish forest nurseries with the hope that in time to come the area may be reforested by artificial means. This feature is expected to prove a very good object lesson to the settlers, who it is hoped will in turn plant windbreaks around their farms.

THE relation between the increasing use of cement and the diminishing timber supply in the United States has been the subject of some correspondence between the Geological Survey and the Forest Service at Washington. In a letter to the forester, the director of the survey took occasion to quote from a statement of a large Philadelphia firm to the effect that it would be difficult to estimate what the additional drain on the lumber supply would have

been during the last few years had not cement come into such general use. The forester replied in part as follows: "The Forest Service is watching with a great deal of interest the increasing use of cement and other substitutes for wood. They are undoubtedly having some influence on the price of lumber, though I do not think that up to the present time they have greatly retarded the advance in lumber prices. The fact is that our industrial progress has been so great that our requirements for every kind of structural material have increased tremendously. We are using at the present time more lumber per capita than ever before and probably twice as much per capita as we did fifty years ago. The conclusion can not be escaped, therefore, that in the future we must depend more than in the past on other materials than wood for certain purposes at least. As to the increase that will take place in the production of cement, my impression is that this will be very great." If the increase in the use of cement in the United States in past years is to be regarded as any index to its future use, the conclusions of the forester are well founded. The statistics of the production of minerals show that our output of cement has more than doubled in the last five years, and it is well known that its use is being very widely extended. This is due to two conditions: In the first place, excellent cement materials are common in almost all sections of the country; in the second place, reinforced concrete for heavy building material is receiving increased favor among engineers, while in the country regions large amounts of cement are being used for building blocks for smaller structures. Reports received by the survey during the six years from 1902 to 1907 show that the production of cement in the United States has increased from 25,000,000 barrels, valued at approximately \$25,000,000, to 51,000,000 barrels, valued at \$55,000,000, the annual statistics showing a steady increase in production with some slight fluctuations in price.

THE western phosphate lands recently withdrawn from entry by the Secretary of the Interior in accordance with the President's

order comprise portions of Morgan, Rich and Cache counties in Utah; portions of Bear Lake, Bannock, Bingham and Fremont counties in Idaho; and nearly all of Uinta County in Wyoming—in all about 7,500 square miles of land more or less underlain by phosphate rock and constituting the greatest known phosphate deposit of the world. Phosphoric acid is an essential constituent of productive soil. Work at agricultural experiment stations in Wisconsin, Ohio and Illinois has shown that in fifty-four years the cultivated soils of those states have been depleted of one third of their original content of phosphoric acid, or at an annual rate of about 20 pounds per acre. Even if the loss has been only one half this amount it would require 6,000,000 tons of phosphate rock annually to offset this depletion in the 400,000,000 acres of cultivated lands in the United States, without allowance for increase in the area cultivated or in the agricultural yield. The list of lands to be withdrawn was furnished by the United States Geological Survey as a result of preliminary examinations made in the field. Further work will be done by the survey as soon as practicable, for the purpose of making a careful classification of the lands and restoring to agricultural entry such portions as may contain no phosphates. It is pointed out by the survey that the situation of this western field is most favorable. The smelters at Butte and Anaconda give off gases, chiefly sulphurous, which are very injurious to vegetation. These gases can be utilized to great advantage by converting them into sulphuric acid for the manufacture of superphosphate fertilizer, thus transforming a substance that is injurious to vegetation into one that is beneficial.

A LETTER to *Nature* signed "T" reads as follows:

The council of the Chemical Society, at a recent meeting when it was determined to exclude women from the fellowship, but to admit them to the society as "subscribers," decided, "after mature deliberation"—the phrase is the senior secretary's—that the appellation "subscriber" should be printed with a big S!

Daughters of Eve! So zealous to pursue
The work in Life by which you seek to live!

When F.C.S. you claim, as is your rightful due—
The S alone is what they, grudging, give!
Be patient! Time is on your side.
Reason and justice will your cause defend.
Ignoble spite and arrogance of pride
Shall meet their retribution in the end!

UNIVERSITY AND EDUCATIONAL NEWS

MR. GEORGE M. LAUGHLIN, of Pittsburg, has bequeathed, in addition to \$125,000 to the hospitals of the city, \$100,000 to Washington and Jefferson College.

THE authorities of University College, Bristol, as part of the scheme to establish a University for the West of England, have purchased the Blind Asylum and its lands, which adjoin University College.

IN memory of the late Sir George Livesey, it is proposed to establish a professorship of fuel and gas engineering at Leeds University, for which purpose at least £10,000 will be collected.

DR. F. W. EURICH has been appointed professor of forensic medicine in the University of Leeds.

DR. MAX RUBNER, professor of hygiene at Berlin, will succeed Professor W. Engelmann as professor of physiology.

As successors of Professor Haeckel, at Jena, the faculty has proposed Professor Lang, of Zurich, Professor Kückenthal, of Breslau, or Professor Platte, of Berlin. It is said that Professor Platte will be selected by the administration.

DISCUSSION AND CORRESPONDENCE

LIGHTS ATTRACTING INSECTS

TO THE EDITOR OF SCIENCE: In the issue of SCIENCE of December 4, 1908 (N. S., Vol. XXVIII., pp. 797, 798), Mr. Owen Bryant states certain observations and asks certain questions regarding the reaction of insects to lights from different sources. As to the relative efficiency in attracting insects of mercury vapor lights, flaming arc lights using sodium carbons, and ordinary arc lights, *when all are of the same area*, I can give no information, nor am I aware that accurate tests of this nature have been made. In a general way, however, it is probable that Mr. Bryant's view

that the light of shorter wave-lengths has more effect is correct, since it has long been known that certain insects, such as ants, give little or no response to red light. This is generally true for the lower organisms, even including *Amoeba*.

But Mr. Bryant has made the common mistake of considering only the intensity and quality of the lights and not taking the *area* into consideration. His observations are very similar to those of Loeb,¹ who found that a certain crepuscular moth (*Sphinx euphorbiae*), when liberated in a room lighted on the one side by a window and on the other by a kerosene lamp, always flew to the window unless it was very close to the lamp when set free. Parker² made further experiments on the same phenomenon in *Vanessa*, and I have elsewhere published³ the results of experiments on several species of insects and a number of other animals, whose reactions were tested to two lights of the same quality and equal intensity, but of different area. The general result was that positively phototropic animals possessing image-forming eyes, such as the butterflies and moths, reacted by going much more often toward the larger light. This would seem to explain the observations of Mr. Bryant in the room, and might possibly apply to some of the kinds of lamps he mentions. At any rate, it shows the necessity of keeping in mind the factor of the *size* of the sources of illumination as well as the intensity and quality of the light they give. In considering size the large globe (as in the case of the arc light) and other parts or adjacent surfaces that reflect light must be taken into account.

EDUCATION AND THE TRADES

TO THE EDITOR OF SCIENCE: I was much interested in the letter of Stella V. Kellerman in your issue of November 18, in relation to "Education and the Trades." Her words "Only by teaching honestly what the world needs, and can use, may the schools accomplished their lofty aims" should be taken as a motto by educational leaders and authorities the world over. I should like to ask a question which I hope some day to see answered in SCIENCE:

Suppose a poor man is enabled by close saving to send his son to a high school "to get an education." The boy does not know what he is "going to be," has no ideas of any trade, business or profession, but he wants to be "educated," and is an average student. There may be hidden in this boy a Lincoln, a Carnegie, an Edison or a Rockefeller. He may have it in him to become a book-keeper at \$1,000 a year, or a good mechanic at \$3 a day. No one knows. By the time he gets through high school he may have acquired the ambition to go to college, or he may be tired of school and want to "go to work" at anything that turns up. *This is the average high school boy.*

What should be the high school curriculum for such a boy? If the elective system is in vogue who shall make the election for him, and on what basis or theory shall it be made, so as *not to waste the time* of the boy while he is in the high school? WM. KENT

THE NEW YORK SERIES

TO THE EDITOR OF SCIENCE: In view of the fact that my article on revision of the New York Series¹ is apparently much antedated by Dr. Grabau's paper before the New York Academy,² may I ask space to explain that my manuscript, exactly as printed, was submitted for publication the last of December, 1907, one week before Dr. Grabau's paper was read. A comparison of the two papers will reveal the changes necessary in my table to give proper recognition to the names introduced by Dr.

Grabau, which thus acquired priority of publication.
GEORGE H. CHADWICK

SCIENTIFIC BOOKS

A Text-book on Roads and Pavements. By FREDERICK P. SPALDING, Professor of Civil Engineering, University of Missouri, Member American Society of Civil Engineers. Third edition, revised and enlarged. New York, John Wiley & Sons. 1908.

This book was first issued in 1894 while Professor Spalding was connected with Cornell University. A second edition was published in 1903. The many changes in methods of construction and maintenance, due in part to new traffic conditions, has made it necessary for the author to practically rewrite several chapters for this third edition. In this, as in former editions, the author discusses the principles involved in the construction and maintenance of the various kinds of streets and roads. The first chapter, on road economics and management, contains, among other things, some interesting paragraphs on tractive resistance, in which is given a valuable table showing the relative loads a horse can draw on different kinds of roads and on grades from one to fifteen per cent. This chapter also contains articles on the economic value of better roads, sources of revenue and systems of road management. The second chapter deals with drainage of streets and roads and contains a table showing the proportions and dimensions of materials used in building reinforced concrete culverts of different sizes. This table should be of especial value to highway engineers and road builders. The third chapter relates to the location of country roads, and is treated from an engineering as well as from a practical standpoint. Chapter four, on the improvement and maintenance of country roads contains information on the building of earth roads, the use of the split-log drag, best methods of building gravel, oil, sand-clay and burnt-clay roads, and the advantages of wide tires. Broken-stone roads are considered in chapter five, which contains articles on the macadam and Telford methods of construction, rock for road building, methods for testing materials, main-

¹ SCIENCE, No. 715, p. 346, September 11, 1908.

² SCIENCE, No. 694, p. 622, April 17, 1908.

tenance of roads, bituminous macadam, etc. The theory and practise of foundations for pavements are presented in chapter six. Chapter seven relates to brick pavements, and contains complete information as to the most approved method of testing paving brick, and the construction and maintenance of brick pavements. The use of asphalts and bitumen in paving is discussed fully in chapter eight. The treatment and testing of wood blocks and the construction of streets of this material are treated in chapter nine. Chapter ten presents the most approved method of building pavements of granite and sand-stone blocks. The eleventh and last chapter presents various methods of arranging city streets so as to best accommodate the traffic. This is a practical book, and is advanced in character. On the whole the author covers his subject well. However, the first chapter could have been more complete, especially the portions relating to the economic value of good roads, cost of wagon transportation, and the benefits derived from road improvement. In the paragraphs relating to the testing of road materials, Mr. Spalding draws from what appears to be the latest published information on the subject, and fails to include a number of important improvements which have been made recently by road-material laboratories, notably the Office of Public Roads in Washington, both in testing machines and in the methods of testing road materials. The chapters on brick and bituminous pavements are probably the strongest features of the book.

ALLERTON S. CUSHMAN

SCIENTIFIC JOURNALS AND ARTICLES

The *American Naturalist* for December has as its first article a paper on "Some Physiological Effects of Radium Rays" by Charles S. Gager, the author concluding that, up to a certain point the effect of radium is to stimulate growth, while beyond that it causes retardation or death. W. A. Cannon discusses "The Origin of Structures in Plants" and Braxton H. Guilbeau the "Origin and Formation of the Froth in Spittle Insects." His conclusion is that this is made up from two

sources; the fluid portion being the anal secretion into which air is introduced by the caudal appendages, while the mucilaginous part is secreted by the glands of Batelli. William A. Hilton has a note, with an illustration, of "Peculiar Abnormal Teeth in a Jack Rabbit"; David Starr Jordan furnishes an unusually large number of "Ichthyological Notes," relating to many papers, and H. E. Jordan gives a "Digest of C. Correns's Memoir on the Inheritance of Sex in Higher Plants." The number is accompanied by the index to Vol. XLII.

Bird-Lore for November-December has articles on "The Sea Birds' Fortrees (Bird Rocks)," by A. C. Bent; "The Drumming of the Ruffed Grouse," by E. J. Sawyer, with a picture from life; "The Use of a Blind in the Study of Bird Life," by Frank M. Chapman; "A Thrasher Friend," by Emeline Maddock and the seventh paper on "The Migration of Fly-catchers," by W. W. Cooke. The number contains the Report of the Annual Meeting of the National Association (of Audubon Societies) and the Reports of State Societies. This portion of *Bird-Lore* has grown in size and importance and now constitutes one half the number.

BOTANICAL NOTES

NOTES ON RECENT GENERAL PAPERS

PROFESSOR H. M. RICHARD's admirable lecture on "Botany" delivered in the Science, Philosophy and Art course at Columbia University is a concise answer to the questions as to the content and scope of the science of botany. Answering the question that it considers "all the questions as to the form, the functions, the classification and distribution" of plants, the author rapidly sketches the history of the science from Aristotle to Darwin in a few pages, and then discusses the present aspects of the different departments of the subject. Its reading will well repay any botanical student who wishes to be better informed as to the place that botany fills to-day in the world of science.

Here may be noted Mr. B. C. Gruenberg's thoughtful paper on "Some By-products of

"Biology Teaching" in the *Proceedings* of the New York Science Teachers' Association for 1907. The writer of these notes would commend it to those young (and old) teachers of biology who think that the subject has value for its content only.

Two little pamphlets for students are Professor Wilcox's "Laboratory Guide to the Study of Elementary Botany," and Professor Clements's "Guide to the Trees and Shrubs of Minnesota." The first is evidently intended for students in such schools as can yet make only rather limited use of the compound microscope and where the laboratory work is necessarily confined to gross anatomy and simple physiological experiments. It must prove useful for the class of students for which it is intended. The second booklet (of twenty-eight pages) succeeds by means of keys and brief descriptions in making it easy for any student of botany to make out the name and relationship of any tree or shrub in the state of Minnesota. Its helpfulness for all classes of botanical students is obvious at a glance.

An instructive and helpful paper for teachers and students of botany is Professor Ramaley's paper on "The Botanical Gardens of Ceylon" in the *Popular Science Monthly* for September, 1908. Eight half-tones from photographs help the readers to obtain a better idea of the rich vegetation of the island.

While not necessarily confined to botany, Mr. O. F. Cook's paper on "Methods and Causes of Evolution" contains so much that bears upon botanical problems that it should be found in every botanist's library. It is a most significant fact that this was published as a contribution to agriculture! What would the farmers just before the civil war have thought if any one had suggested that in half a century they would be practising evolution according to Darwin!

Allied to the foregoing is the same author's paper on the "Reappearance of a Primitive Character in Cotton Hybrids," giving some

¹ Bull. 136, Bureau of Plant Industry, U. S. Dept. Agric.

² Circular 18, Bureau of Plant Industry.

individual results of experiments for the purpose of acclimatizing certain weevil-resistant varieties of cotton.

In January, 1905, Captain John Donnell Smith, of Baltimore, presented his herbarium and botanical library to the Smithsonian Institution. The former, consisting of more than 100,000 specimens, became a part of the National Herbarium. Now we have a catalogue of the library of 1,600 bound volumes,* which will be very helpful in giving exact titles of many rare books.

CHARLES E. BESSEY

SPECIAL ARTICLES

NOTE ON SOME NEW JERSEY FISHES

A YOUNG example of *Lactophrys triqueter* was taken at Grassy Sound, on September 18, 1904, and presented to me by Mr. R. M. Miller. This is the first instance of this species occurring in New Jersey waters. Dr. R. J. Phillips obtained an interesting collection at Corson's Inlet, among which were examples of *Anchovia brownii*, *Hyporhamphus unifasciatus*, *Trachinotus falcatus*, *Lagodon rhomboides*, *Bairdiella chrysura*, young *Micropogon undulatus*, *Stephanolepis hispidus*, *Myoxocephalus æneus*, *Rissola marginata* and *Ammodytes americanus*. The last was very abundant, and many examples of large size were found. An example of *Merluccius bilinearis* was secured at Ocean City, in Great Egg Harbor Bay, on July 26, by Mr. D. McCadden. In this connection I might mention that Mr. O. H. Brown secured an example of the four-toed salamander, *Hemidactylium scutatum*, at Cape May, on July 20, which is the first record of its occurrence in the lower half of the state.

ACADEMY OF NATURAL SCIENCES,

PHILADELPHIA,

December 17, 1908

SOCIETIES AND ACADEMIES

THE NEW YORK ACADEMY OF SCIENCES

The academy held its annual meeting Monday evening, December 21, 1908, at the Hotel Endicott,

* Contrib. U. S. National Herbarium, Vol. XII., Pt. 1.

about seventy-five members and their friends being in attendance.

The report of the recording secretary showed that during the year 1908 the academy had held eight business meetings and twenty-eight sectional meetings, at which ninety-six stated papers and four lectures had been presented, classified under fourteen branches of science; furthermore, that four public lectures by noted home and foreign scientists had been given at the American Museum of Natural History to the members of the academy and the affiliated societies and their friends. Attention was called to the preparations under way for the celebration, on February 12, 1909, of the centenary of the birth of Charles Darwin and the semi-centennial anniversary of the appearance of "The Origin of Species," which promises to be an event of more than ordinary importance to the local scientific public. This report also stated that the membership of the academy was now 458 active members, including 127 fellows and 12 associate active members, a net loss of 42 active members during the year 1908.

According to the report of the corresponding secretary, the academy has lost by death during the past year the following honorary members: Lord Kelvin, elected in 1876; Professor Charles A. Young, elected in 1878; Professor Wolcott Gibbs, elected in 1899; Professor Wm. K. Brooks, elected in 1898; Professor Amph Hall, elected in 1899; and the following corresponding members: Professor Daniel C. Gilman, elected in 1876; Professor Albert de Lapparent, elected in 1900; Professor Albert B. Prescott, elected in 1876; Colonel Aimé Laussedat, elected in 1890. There are now upon our rolls the names of forty-five honorary and 142 corresponding members. At the meeting three honorary members were elected, namely: Dr. Eduard Strasburger, professor of botany in the University of Bonn; Professor Kakichi Mitukuri, director, College of Science, Imperial University, Tokyo, Japan; Dr. Wilhelm Ostwald, of the Royal Society of Natural Science, Leipzig, Germany; and the following active members were elected fellows: Dr. Charles P. Berkey and Dr. Charles L. Pollard.

The treasurer's report showed that the financial condition of the academy was satisfactory.

The officers of the academy desire to call the attention of the members to the fact that the academy has in its keeping two important funds, the income of which is available for the encouragement of scientific research. These are the Esther Herrman Building Fund and the John Strong

Newberry Fund. Grants are made to members of the academy or of the affiliated societies upon application to the council of the academy with the endorsement by the society of which the applicant is a member. During the past year more than one thousand dollars was paid out from the Esther Herrman Research Fund on account of such applications, and the reports presented by the grantees show the importance of the assistance granted. Income is now available for appropriation upon approved application.

The librarian's report showed that during the past year the library of the academy has received through exchange and donation 454 volumes, 32 separate and 1,863 numbers. The chief accessions were a gift of 40 volumes from La Société des Naturalistes de Varsovie and of 71 volumes from the Sociedad de Geographia, Lisbon. The books may be consulted by members and the public any week day between the hours of 9:30 A.M. and 5 P.M., and members are urged to assist in extending the use of the library.

According to the editor's report, part 3 completing volume XVII. was distributed early in the year and parts 1 and 2 of volume XVIII. have been printed and distributed, while two parts of part 3 of volume XVIII. have been printed but not distributed. Part 1 of the latter volume was devoted to the records of the Linnaeus celebration of May 23, 1907, including the addresses delivered on the occasion and the greetings received from sister organizations at home and abroad.

The annual election resulted in the choice of the following officers for the year 1909:

President—Charles F. Cox.

Vice-presidents—J. J. Stevenson, Frank M. Chapman, D. W. Hering and Maurice Fishberg.

Recording Secretary—Edmund Otis Hovey.

Corresponding Secretary—Hermon Carey Bum-pus.

Treasurer—Emerson McMillin.

Librarian—Ralph W. Tower.

Editor—Edmund Otis Hovey.

Councillors (three years)—Franz Boas, Henry E. Crampton.

Finance Committee—Charles F. Cox, George F. Kunz and Frederic S. Lee.

After the business meeting, the members of the academy and their friends sat down together at the annual dinner, at the conclusion of which the president, Mr. Charles F. Cox, gave an address upon "Charles Darwin and the Mutation Theory."

E. O. Hovey,
Recording Secretary

THE PROBLEM OF SEVERAL BODIES: RECENT PROGRESS IN ITS SOLUTION¹

I

THE DIFFERENTIAL EQUATIONS AND THEIR TRANSFORMATIONS

WHITTAKER has formulated the classic problem of three bodies as follows: Three bodies attract each other according to the Newtonian law so that between each pair of particles there is an attractive force which is proportional to the product of the masses of the particles and the inverse square of their distances apart: they are free to move in space and are initially supposed to be moving in any given manner; to determine their subsequent motion.

In mathematical phraseology the problem is to integrate a certain system of the eighteenth order of differential equations which at present are usually written in the so-called canonical form

$$dx_i = \frac{\partial F}{\partial p_i} dt, \quad dp_i = -\frac{\partial F}{\partial x_i} dt,$$

in which t is the time, x_i a coordinate, p_i a component of momentum, and F a certain function of all the x_i and p_i .

In recent investigations, especially those originating in the researches of Poincaré, the canonical equations are preferred to other types because of their simplicity of

¹ Abstract of the address of the vice-president and chairman of Section A—Astronomy and Mathematics—American Association for the Advancement of Science, Baltimore, 1908.

form, ease of transformation and perspicuity in showing how the variables enter the problem. It becomes of advantage, then, to expand the function F in terms of canonical elements; Charlier has given in his lectures a method of expansion which Norén and Wallberg carried out to terms of the second degree. Stone has published a simple direct derivation of the canonical elements introduced into the three-body problem by Delaunay and Jacobi; while the formulæ of transformation from Cartesian to Jacobian coordinates in the n -body problem have been derived by Pizzetti with the aid of linear substitutions.

From the standpoint of the theory of integral invariants introduced by Lie and Poincaré the characteristic property of the canonical system is the existence of the relative integral invariant $\int \Sigma x_i dp_i$, and the covariant correspondence between the canonical system and the differential expression $\Sigma x_i dp_i - F dt$ forms the connection between their theory and that of contact transformations. A systematic study of integral invariants has been published by De Donder, including his own researches and those of Appell, Hadamard and Koenigs. Morera has shown in a series of memoirs how this transformation theory gains in generality, simplicity and elegance when at its foundation we lay the bilinear covariant correspondence to which allusion has just been made; Morera rediscovers and generalizes the theorems of Lie on the invariance of canonical systems under contact transformations. The importance of these results for the problem in hand is recognized when we recall that Lagrange's method of the variation of arbitrary constants in the theory of perturbations leads to equations of the canonical form; Lie's theory thus stamps the history of a perturbation problem as the history of a contact transformation, a rela-

tion exhibited on the geometrical side by the true orbit enveloping the successive approximate ones. The notion of an intermediate orbit has been extended to canonical systems by Charlier, who has employed it in a generalization of Jacobi's theorem.

Lagrange showed that the eighteenth order system in the three-body problem can be reduced to one of the sixth order; this reduction has been effected in a variety of ways by other mathematicians. Poincaré employed a contact transformation to reduce the problem to the twelfth order, and Whittaker has used an extended point transformation to carry the reduction on to the eighth order. Whittaker has also exhibited in explicit form the contact transformations involved in Radau's direct reduction from the eighteenth to the sixth order. Routh's transformation known as the ignorance of coordinates has recently been generalized by Woronetz to a form which includes as special cases Poincaré's equations of motion, and the reductions of Lagrange, Jacobi, Bour and Brioschi. The discovery of the existence of a force center in the three-body problem has enabled Delaunay to write its equations in a special form. Scholz has shown that under certain assumptions regarding the perturbative function the three-body problem can be reduced to the integration of a single differential equation, and a new reduction of the plane problem has been given by Perchot and Ebert. The corresponding reduction of twelve units in the order of the n -body problem has been effected by Bennett through Poincaré's transformation and a generalization of the one employed by Whittaker in the three-body problem.

In the transformation and reduction of the problem a principal rôle has been played by the ten known integrals, namely, the six integrals of motion of the center of gravity, three integrals of angular mo-

mentum, and the integral of energy. The question of further progress in this reduction is vitally related to the non-existence theorems of Bruns, Poincaré and Painlevé. Bruns demonstrated that the n -body problem admits of no algebraical integral other than the ten classic ones, and Poincaré proved the non-existence of any other uniform analytical integral. A strikingly instructive example illustrating these non-existence theorems has been given by Perchot and Ebert. Painlevé has generalized Bruns's theorem by showing that, in addition to the classical integrals of energy and momentum, there exists neither integral nor integral equation algebraic in the velocities, and the theorem of Poincaré, by proving that there exists no new analytical integral uniform with respect to the velocities. Gravé showed that the three-body problem under forces varying as any function of the distance possesses no new integral independent of the law of attraction, and this theorem has been generalized for the n -body problem. Bohlin has very recently added to the non-existence theorems by demonstrating that the mutual distances in the problem of three bodies can not be expressed as the roots of an algebraical equation of the fifth degree with transcendental coefficients.

II

PARTICULAR SOLUTIONS AND THEIR GENERALIZATIONS

In 1772 the prize of the Académie Royale des Sciences de Paris was awarded to Lagrange for an "Essai sur le Problème des Trois Corps." In this celebrated memoir Lagrange "shows that the complete solution of the problem requires only that we know at each instance the sides of the triangle formed by the three bodies; the coordinates of each may then be determined without difficulty. As for the solution of the triangle, it depends upon three

differential equations, of which two are of the second order, the third of order three." He determined all the solutions of the problem in which the ratios of the mutual distances of the bodies remain constant. In one of the two distinct configurations the bodies are always at the vertices of an equilateral triangle; in the other they lie always on a straight line. In both of these cases the motion of each body relative to either of the others is the elliptic motion of the two-body problem. Tscherny has constructed these solutions geometrically; he has also shown that the only cases of the three-body problem for which known mathematical and mechanical means suffice are those which reduce to the problem of two bodies. Lagrange's solutions were originally discovered in his problem of the mutual distances; the latter, called by Hesse the reduced problem, has recently assumed a new form under Charlier's treatment, in which the mutual distances are replaced by the distances from the center of gravity. From Lagrange's discussion certain imaginary considerations were omitted; Whittemore has filled this gap, but the completed discussion yields no other real solution. The equilateral triangular solution is possible for all distributions of the masses; their distribution on the straight line is defined by the real positive root of a certain quintic equation; Frederigo has given a new derivation of this equation and Bohlin has formulated four developments, of which three represent the roots of the quintic in three distinct domains, and the fourth for an isolated value. The question of the stability of the solutions furnishes Levi-Civita an example of his theory of stationary motion in which reappear the results of Liouville and Routh, namely, the triangular solution is stable if

$$(m_1 + m_2 + m_3)^2 > 27(m_1m_2 + m_2m_3 + m_3m_1),$$

while the rectilinear solution is always unstable.

Theoretical interest in the Lagrangian solutions has been increased by Sundman's theorem that the more nearly all three bodies in the general problem tend to collide simultaneously, the more nearly do they tend to assume one or the other of Lagrange's configurations; and on the other hand practical interest in them has been revived by the discovery of three small planets, 1906 T.G., 1906 V.Y., 1907 X.M., near the equilateral triangular points of the Sun-Jupiter-Asteroid system. Linders has begun the investigation of the motion of the first of these by starting from a periodic solution of the differential equations and developing the Jupiter perturbations from the osculating elements.

Lehmann-Filhés, Hoppe and Dziobek have generalized the exact solutions to cases of more than three bodies placed on a line or at the vertices of a regular polygon or polyhedron, and isosceles triangular solutions have been studied by Fransen, Gorjatschew and Woronetz, while Longley in an investigation of the plane problem of invariable configuration pays special attention to the rhombus. The cases considered by Dziobek and Lehmann-Filhés have been generalized by Pizzetti in a direct study of the homographic motion of n bodies. Among the most interesting extensions of Lagrange's theorem are those due to Banachiewicz and Moulton. The former considers a non-equilateral triangular system with fixed center of gravity and under attractions according to the inverse cube of the distance. He finds a particular solution in which the triangle rotates around the x -axis, its angles remaining constant, and each point describing a curve on a cone of revolution about the same axis which projects into a spiral on the base of the cone. This is the first case of an exact solution in which

three finite bodies describe curves of double curvature. Moulton's case is that of the four-body problem consisting of three arbitrary masses, in motion according to either of Lagrange's solutions, and an infinitesimal body; there are eighteen solutions of arbitrary period in which the finite bodies lie on a line, and ten in which they are at the vertices of an equilateral triangle. Periodic solutions analogous to those in the restricted three-body problem have been constructed for Moulton's problem.

The method of Lagrange's memoir has been extended to the four-body problem by Seydler and more recently by Woronetz; the latter has pointed out particular solutions in which three of the bodies are equal; these solutions are given by quadratures if the law of force is inversely as the cube of the distance and are capable of direct extension to the case of any number of bodies.

III

PERIODIC SOLUTIONS AND THEIR APPLICATIONS

The Lagrangian solutions remained the only known periodic solution of the problem of three bodies for one hundred and five years until 1877, when Hill, in his epoch-making researches on the lunar theory, demonstrated the existence of a periodic solution which could serve as the starting point for a study of the moon's orbit. With these memoirs he broke ground for the erection of the new science of dynamical astronomy whose mathematical foundations were laid broad and deep by Poincaré. Up to the time when Hill's work appeared, mathematical astronomers were accustomed to assume a solution of the problem of two bodies as a first approximation in the lunar theory; which intermediate orbit includes none of the inequalities due to the sun's disturbing

force. Hill proposed to take as this first approximation an orbit which would include all the inequalities depending upon the mean motions of the sun and moon. The old theories consisted essentially in suitably varying a solution of the problem of two bodies, while Hill's theory seeks the true orbit by attempting to vary appropriately the restricted problem of three bodies. During the last fifteen years, Brown has published a series of papers, concluding with the 1907 Adams Prize Essay of the University of Cambridge, which extend Hill's work to the construction of the most perfect of all the ten or eleven theories of the moon which have appeared since Newton's "Principia." Hill found periodic solutions of the motion of a particle in a plane under the influence of two bodies which revolve round each other in circular orbits and whose distance apart is infinite. In its initial stages Brown's theory modified Hill's solution in two particulars, first by reducing the distance of the two bodies to finite dimensions, and thus introducing the inequalities which involve the solar parallax, and second by including those inequalities which are due to the moon's eccentricity. Adequate accounts of these theories are given in the presidential addresses delivered on the occasions of the award of the gold medal of the Royal Astronomical Society to Hill in 1887, and to Brown in 1907, while the relations of Brown's perfected work to the highly original pioneer work of Hill are exhibited in the introduction which Poincaré has written to Hill's "Collected Works." Brown has recently finished his complete numerical theory, and lunar tables based upon it are to be published by Yale University. His numerical results furnish an interesting confirmation of the validity of Newton's law. Newcomb proposed an explanation of the motion of Mercury's perihelion by changing the ex-

ponent 2 in the Newtonian law to $2 + 0.00000016$. Brown finds in his theory of the moon's motion that the exponent can differ from 2 only by ± 0.00000004 .

The work reviewed up to this point in our discussion has found its sources in Hill's periodic solution, the memoir of Lagrange, the non-existence theorems of Bruns and Poincaré, and Lie's theory of contact transformations; that which follows may trace its origins to Poincaré's theoretical and Darwin's numerical investigations on periodic solutions, Newcomb's and Lindstedt's solutions in trigonometric series, Gylden's theory of absolute orbits, and Painlevé's theorems on the singularities of the problem.

Although periodic and asymptotic solutions do not exist in nature their services to astronomy have been two-fold: to the practical astronomer in supplying first approximations to orbits under investigation, and to the mathematical astronomer in opening the way to further theoretical researches through what Poincaré has characterized as "*la seule brèche par où nous puissions essayer de pénétrer dans une place jusqu'ici réputée inabordable.*" Darwin has constructed a splendid collection of examples of these orbits, planetary and lunar; among his most curious satellite orbits are perhaps those which present three new moons in a month, and another which has five full moons in one period. Darwin's orbits were subjected to a searching analytical examination by Poincaré who showed that two sets of curves which Darwin treated as continuous can not be considered as such; the true sequence of the orbits in question has been exhibited by Hough. Certain of Darwin's results have been derived analytically by Charlier, and specially with reference to the families of oscillating satellites in the vicinity of the five centers of libration corresponding to the exact Lagrangian solutions. In Char-

lier's paper no account was taken of the imaginary centers of libration; the analytical treatment was completed in this particular by a note which showed that there are imaginary centers about which real orbits exist. Plummer has extended Charlier's analysis to arbitrary fields of force, and to terms of the second and third orders in the developments. Schlitt has reckoned five orbits to whose construction Darwin referred as not belonging to the category of simply periodic orbits, and for that reason disregarded by him. With Darwin's orbits Moulton has compared certain of his own, established by Poincaré's method of analytical continuation, and arranged in power series rather than Fourier series. Finally to Darwin's orbits Strömgren has applied his conditions for cusps and loops in the restricted three-body problem; Strömgren has shown that these singularities may be encountered in every point in the plane, in the absolute motion as well as in that referred to moving axes.

Periodic orbits have been variously classified. If the curves are reentrant after a single period Darwin calls the orbits "simply periodic"; all the orbits considered by him have this property. Hill has grouped them broadly into two classes: the first contains those in which a rotation of the whole system has taken place; the second, those in which no such rotation has occurred, but the longitudes of the bodies and their distances have returned to the same values. Poincaré has classified them elaborately into species, classes and kinds, but as Charlier has pointed out this classification is not exhaustive. The great majority of the orbits referred to here belong to the first two kinds, as distinguished by Poincaré, that is, they either have inclination and eccentricity zero or inclination zero and eccentricity not zero. Von Zeipel has published

a thorough study of the solutions of the third kind—that is, those having both inclination and eccentricity different from zero—in which they are grouped in no fewer than ten types and their stability discussed by the aid of their characteristic exponents. Whittaker has designed a criterion for the discovery of periodic orbits analogous to those theorems which indicate the positions of the roots of an algebraic equation.

A matter of vital theoretical and practical import in the domain of periodic solutions is the question of their stability. Following Poincaré's lead, Brown has formulated the sufficient conditions for stability in the n -body problem as follows: first, that the bodies never become infinitely distant from one another; second, that their mutual distances never descend below a certain limit; third, that each body passes an infinite number of times as near as we wish to any point through which it has once passed; fourth, that a small external disturbance shall not affect the fulfillment of these conditions. Poincaré stated the first three and investigated the third in detail; numerical limits for the first and second have been found by Haffel in a particular case of the sun-earth-moon system. Levi-Civita has worked out criteria in which the stability is made to depend upon that of a certain point transformation associated with the periodic solution; these criteria show the instability of certain orbits which in the first approximation appear to be stable; they indicate further that contrary to accepted opinion a purely imaginary characteristic exponent α does not always single out a stable solution—the solution is unstable if $\alpha/\sqrt{-1}$ is not commensurable with the mean motion $2\pi/T$. Applying his method to the restricted problem Levi-Civita has found that solutions differing little from circles and having a mean motion $1 + 3/h$ are certainly unstable, thus

proving the existence of zones of instability surrounding Jupiter's orbit which may extend throughout the plane. The above conditions are approximately satisfied for the small planets (167) Urda, (243) Ida, and (396) whose mean motion is near $1 + 3/2$ and whose eccentricities and inclinations are very small; the planet (188) Menippo has a mean motion near $5/2$, but an inclination and an eccentricity too large for these considerations to be immediately applicable. Kobb has called the attention of astronomers to the fact that he found the orbit of (153) Hilda to be stable but that the conditions for stability are not satisfied by the motion of (279) Thule; the same writer has shown the motion of the seventh satellite of Jupiter to be stable and that of the eighth unstable, while Moulton has established limits of temporary stability for satellite motion. Levi-Civita's criteria have been studied by Cigala, and those of Lehmann-Filhés for circular motion have been generalized by Frank. Gray has given a résumé of the work of Charlier, Hill, Picart, Roche and Schiaparelli on the stability of a swarm of meteorites and of a planet and satellite, and Routh has discussed the motion and stability of a swarm of particles whose center of gravity describes an elliptic orbit of small eccentricity about the sun. Considering a system composed of a planet, a rigid ring, and a satellite Bohl has proved that under certain initial conditions the motion can be terminated only by a ring planet collision; further, that the possibility of the latter collision may be excluded and permanent stability secured.

The new methods in celestial mechanics have proved their usefulness in computing the perturbations of those small planets whose period of revolution is approximately commensurable with that of Jupiter. To enumerate: Simonin has applied Poincaré's methods to the case of Hecuba

and has succeeded in obtaining a very close solution by means of simple expressions; Hill has devoted two memoirs to examples of periodic solution in studies primarily concerned with cases of mean motions respectively triple and double (Hecuba type) that of Jupiter; Poincaré has shown the essential agreement between his own results and those of Brendel's "*Theorie der kleinen Planeten*" constructed along the lines of Gylden's method; Hill and Andoyer have applied Delaunay's method to the Hecuba group; Poincaré has exhibited the relations of Simonin's results to the applications of Gylden's method made by Ludendorff to Hecuba, by Brendel to Hestia, and by Harzer to Hecuba; Schwarzschild has made a numerical investigation of periodic solutions in the vicinity of the Hecuba orbit; Wilkens has applied his asymmetric solutions to orbits of the Hecuba type, establishing their stability by Poincaré's method; and finally Wilkens and De Sitter have studied solutions of the Hestia type. A class of periodic solutions was designed by Moulton, and successfully applied to the lunar theory; independently Gylden and Moulton utilized periodic orbits to explain the Gegenschein; and McCallie, following a suggestion of Hill's, constructed an example of periodic solutions from the theory of Jupiter and Saturn. Strömgren found that asymptotic motion towards one of the equilateral triangular centers of libration takes place only under exceptional circumstances, for as a rule the body describes a periodic orbit around this center or recedes indefinitely from it.

In an exhaustive treatment including all the limitation and libration motions of the special case of the three-body problem when two of the bodies are fixed Charlier has noted two applications: first to the case where a small body passes at great speed through a double star system, and second

to the generalization of those conditions which result in the moon revolving about the sun if the earth and sun become fixed centers. Charlier has also considered the relations of the two-body problem to the two-center problem, and has pointed out the advantages of solutions of the latter as intermediate orbits in the asteroid problem. The case where one fixed center attracts and the other repels was worked out in detail by Wöller; and Hillebrandt applied the method of Charlier's work to the qualitative discussion of the most general two-center problem admitting of separation of the variables.

Hill has prepared a number of examples of Gylden's periplegmatic orbits, some of which are periodic. The construction of the solutions calls for elliptic functions, Lindstedt's series, and sequences of Delaunay transformations. These examples of Hill have been generalized in several directions, in one of which certain of Painlevé's new transcendental functions find application. For the case of two nearly equal bodies and a third infinitesimal body Pavannini found a new category of periodic solutions which have been extended to the restricted problem of four bodies. Andoyer's memoir on the relative equilibrium of n bodies has been made by him the basis of a study of periodic solutions in the vicinity of positions of relative equilibrium under forces varying as the masses and any power of the distances. Longley has constructed the only orbits (one direct the other retrograde) of pre-assigned period in the plane n -body problem which consist of an infinitesimal body revolving around one of $n - 1$ finite masses which are in periodic motion. For the plane n -body problem having the same distribution of masses as the solar system, Griffin found a class of periodic solutions of which he has made numerical application to the three inner satellites of Jupiter.

FORMAL AND QUALITATIVE RESOLUTION OF THE PROBLEM

By generalizing somewhat the theory of periodic and asymptotic solutions by which Poincaré established the divergence of Lindstedt's series von Zeipel has been able to study the series, however great the mutual inclination of the orbits may be. He derived the following necessary and sufficient conditions for the existence of the series: first, that the orbits be nearly circular; second, that a certain biquadratic equation have real and unequal roots. Von Zeipel found that if the inclination of an asteroid exceeds a certain limit (about 30° , slightly variable) the series of Lindstedt cease to exist; and he remarked that it is perhaps permissible to see in this theorem, although Lindstedt's series are only semi-convergent, the cause of the surprising fact that among five hundred asteroids there exists but one (Pallas) whose inclination exceeds 30° .

Hill has extended Delaunay's method to the general problem of planetary motion, and, employing the fundamental conceptions of Gylden, he has indicated a practicable way for its application, in two memoirs on integrals of planetary motion, suitable for an indefinite length of time. Charlier has discussed the properties of the general solution in trigonometric series by supposing it to have been derived from the integration of the Hamilton-Jacobi equation. For constructing solutions in the form of trigonometric series, Whittaker has devised a method, closely analogous to Delaunay's, and consisting essentially in the repeated application of contact transformations which ultimately reduce the problem to the equilibrium problem. Bohlin has just published the concluding memoirs of a remarkable series of investigations which have culminated in a non-existence theorem quoted in a previous paragraph, and in his new astronomical series for the distances

and coordinates; these series, both in their terms and in their coefficients, are built up from certain developments which Bohlin has derived for roots of the fundamental quintic met with in Lagrange's problem of the mutual distances.

The question of the validity of certain methods of Gylden has been the source of considerable discussion among mathematical astronomers during the period under review. The appearance of a long memoir by Buchholz on Gylden's horistic method, and its convergence, brought forth from Backlund a protest against the manner in which the material of the memoir had been accumulated and presented. To this protest Buchholz replied with a defense of the course he had pursued in preparing the work; and a little later he published another note objecting to a statement by Schwarzschild that Poincaré, in his prize memoir, had proved the divergency of the series employed by astronomers. About this time Poincaré examined in detail the second of Gylden's two horistic methods, the first being open to grave objections as had been shown by himself and Backlund. As a result of his investigation Poincaré found that the second method, conveniently modified, is a legitimate one, not for the search of the general solution, but for the determination of one of those particular solutions which he himself had termed periodic. He pronounced futile the effort to derive from the horistic method developments uniformly convergent in the geometric sense of the word, and declared false Gylden's conclusion that the terms of high order in the perturbative function can never produce libration. Poincaré's results were questioned by Backlund and an interesting controversy ensued, some points of which were elaborated upon in a later extensive memoir which Poincaré devoted to Gylden's theory, where he pointed out Gylden's great service to science in

creating a number of new methods which have been applied with success to certain problems of mathematical astronomy, as for instance, in the theory of the small planets developed by Harzer and Brendel. He found the methods proposed in Gylden's earlier memoirs to be correct in the main, but possessed of little more than historic interest, having been superseded by less inconvenient methods such as those of Hill and Brown. Gylden's later theories Poincaré subjected page by page to a searching critical examination which resulted in a declaration that they are invalidated throughout by errors arising in the initial stages of Gylden's analysis.

Thanks to the recent researches of Levi-Civita, Bisconcini, Sundman and Block, inspired as they were by an earlier theorem of Painlevé the qualitative solution has been attained in the field of the formal resolution of the mathematical problem of three bodies, and some progress has been made towards the same end in the astronomical problem. Painlevé demonstrated that starting from given initial conditions singularities occur only if one at least of the mutual distances tends towards zero, when t converges to a finite value t_1 . When these singularities have been located, the recent theorems of Mittag-Leffler, on the representation of monogenic branches of analytical functions, warrant the assertion that the coordinates are expressible in every case, and throughout the duration of the motion, in series possessing the fundamental properties of Taylor's series. It may be remarked in passing that Volterra has given examples of the applicability of Mittag-Leffler's developments to certain cases of the general n -body problem. From the standpoint of the qualitative resolution of the problem, it becomes of paramount importance, then, to define with precision the initial conditions which lead to a collision. Painlevé in his Stockholm

lectures announced the opinion that the initial conditions which constrain a collision of at least two of the three bodies at the end of a finite time, satisfy two distinct analytical relations, which reduce to one in the case of plane motion. These analytical relations whose existence Painlevé divined have been disclosed by the brilliant researches of the two Italian mathematicians, Levi-Civita and Bisconcini. Levi-Civita blazed the trail in the restricted problem and found an unique, invariant relation, algebraical in the velocities, periodic and uniform, which he developed in a power series. It may be noted that simple modifications of Levi-Civita's analysis render it immediately applicable to the restricted problem of four bodies. There appears again a single uniform periodic condition for collisions of two of the bodies, and this condition is algebraic in the velocities. The result thus constitutes an exception to Painlevé's theorem that when three of the masses are different from zero the conditions which must be satisfied in the n -body problem in order that after a finite interval of time two of the bodies may collide, can not be *algebraical conditions*. In the general three-body problem Bisconcini, following the route marked out by Levi-Civita in the restricted problem, has arrived at two distinct relations whose analytical form he has determined. Bisconcini has thus been able to characterize all the singular motions of the system in which any two of the bodies collide, and to determine the analytical conditions under which we may be certain that the motion will proceed regularly. One of the assumptions made by Bisconcini in the course of this work has since been demonstrated by Sundman. In a new elaboration of his original memoir Levi-Civita has been able to extend certain of his results to the astronomical, restricted problem. Sundman has found the condition for the simultaneous collision of all

three bodies to consist in a vanishing of all three integrals of areas in the motion of the bodies with respect to their common center of gravity; if the constants of areas are not all zero, Sundman has assigned a positive limit below which, of the three distances, the greatest always remains so. The same writer has announced the extension of his results to the n -body problem, including explicit expressions for the co-ordinates in the vicinity of equilibrium. In the meantime Block has presented to the Swedish Academy of Sciences a memoir in which he has given the developments in powers of the time in Sundman's case of collision; these power series contain terms of three different forms in whose exponents the masses of the bodies appear. The recent memoirs of von Zeipel on intransitive motion in the three-body problem and the indeterminate singularities in the case of n bodies are treated in the report reviewed here. Mittag-Leffler is preparing a memoir soon to be published in the *Acta Mathematica* in which there will appear a digest of Weierstrass's correspondence in its bearing on the problem of three bodies. The memoir will be concerned especially with the relations of this correspondence to the setting of the problem for the prize, offered by the late King Oscar II., of Sweden; to the report on which the award of the prize was based; and to the recent work on the singular trajectories of the general problem of three bodies, and its resolution in power series.

V

GENERALIZATIONS OF THE PROBLEM AND ITS INVERSION

During the period under discussion the problem has been variously generalized. Ebert has formulated an equivalent problem to that of n bodies, with an additional integral; and a similar generalization has been made by extending the Bour-Bertrand

treatment of the three-body problem. Escalagnon and Bohl have indicated applications of quasi-periodic functions to the ordinary problem; special cases in which the masses vary with the time have been considered by Mestchersky; Laves has studied the integrals when the forces depend upon the coordinates and their derivatives of the first two orders; and Ebert has taken up the problem in space of any number of dimensions.

Bertrand inverted the problem of two bodies by proposing to find the law of force under which a body, whatever may be its initial position and velocity, always describes a conic section. This inverse problem was solved independently by Bertrand, Darboux and Halphén; and extended by Dainelli to general curve trajectories. Stephanos has recently given another generalization of Bertrand's problem by including in the discussion the case in which the force has not necessarily an unique direction at every point of the conic section. This problem in turn has been generalized to conditions which include the conic section trajectories as special cases. Griffin observed that the law of force under which a given curve is described as a central orbit can not be determined uniquely if only the position of the center of force be known. Oppenheim gave to Bertrand's problem a new treatment which included the case of finding the central conservative forces under which three bodies of arbitrary mass describe given plane curves.

A further generalization of Bertrand's problem presents itself in the problem of finding the forces of a central conservative system capable of maintaining a system of m particles on as many prescribed but arbitrary orbits in a space of n dimensions. The resolution of this problem shows that the central conservative character of the motion and the equations of the orbits are necessary and sufficient to determine the

components of the velocities, only in the case of $\frac{1}{2}n(n+1)$ bodies, and the components of the forces only in that of $2n-1$ bodies. From this point of view the plane three-body problem possesses an unique generality of its own, in that it is the only case in which all the elements of the mechanics of the problem are completely determinate when the arbitrary plane curves described by the bodies under central conservative forces are given. This circumstance has been turned to account in the construction of new integrable problems of three bodies under laws of force involving only the masses and the mutual distances of the bodies.

HOUSTON, TEXAS

THE PHYLETIC IDEA IN TAXONOMY¹

TO-DAY every botanist is an evolutionist. It may well be that we have not yet agreed as to the details—as to the particular manner in which modifications were effected—whether they were by slow and almost imperceptible deviations from the parental type, or those more marked variations that we are in the habit to-day of calling “mutants.” Some of us may lay more stress upon the “survival of the fittest,” others upon the “survival of the unlike.” For some the “struggle for existence” may account for the diversity of plant forms, while others see in “adaptation” the explanation of the same diversity. To some the “inherent tendency” in plants to vary is a potent factor, while for others all variation is a result of “environment.” Yet with all this diversity of opinion as to details there is a practical unanimity as to the acceptance of the general doctrine of evolution. It may be asserted without fear

¹ Address of the vice-president and chairman of Section G—Botany—of the American Association for the Advancement of Science, Baltimore, 1908.

of contradiction that all scientific botanists hold that the vegetable kingdom as we know it to-day is the result of a series of evolutions from lower to higher types of plants, and that every higher plant owes its present structure to the favorable modification of some ancestral lower plant. To-day when we study the particular structure of any plant we consider it to be the result of the modifications that have taken place in its phylogenetic history. No botanist now considers a species to be a separate or special creation, but rather a more or less distinguishable variation from some other form.

With such an agreement among botanists as to the validity of the doctrine of evolution, it needs no argument to sustain the thesis that a natural classification must be an expression of a theory of evolution. Such taxonomic terms as "higher," "lower," "primitive," "derived," "relationship," "affinity," etc., can have no other significance than that given them by the doctrine of evolution. To-day there are no hidden or occult meanings to be attached to plant structures. We no longer credit the doctrine of signatures, whether in medical or systematic botany. We no longer seek to find the characters which in some mysterious way are the special marks of classes, nor those which are necessarily ordinal marks, or the characteristic marks of families, and so on to genera and species. And yet it is not so very long since a great biologist seriously set about trying to do this very thing. You will remember that Agassiz made this attempt² about fifty years ago, and that he actually formulated his plan in definite terms. I may as well quote the paragraphs in which he states his method of characterizing different groups. They are as follows:

² "An Essay on Classification," by Louis Agassiz, London. The preface dated December, 1858, p. 261.

Branches or *types* are characterized by the plan of their structures;
Classes, by the manner in which that plan is executed, as far as ways and means are concerned;
Orders, by the degrees of complication of that structure;
Families, by their form, as far as determined by structure;
Genera, by the details of the execution in special parts; and
Species, by the relations of individuals to one another and to the world in which they live, as well as by the proportions of their parts, their ornamentation, etc.

With regard to these he says a little later³ that "the branches, the classes, the orders, the families, the genera, the species, are groups established in nature respectively upon different categories," and declares that he feels "prepared to trace the natural limits of these groups by the characteristic features upon which they are founded," that is, upon those which have just been enumerated in my quotation.

In the common systematic characters as drawn up by many botanists in the recent past there has been something of the old-time notion that we are dealing with fixed groups whose limits are indicated to us by certain rather definite structural characters which nature has accommodately attached to all plants in these groups. The thought seems to have been that plants are "tagged" or "branded" with the peculiar marks of the group, these marks having otherwise no particular significance. One is reminded of the similar use which stockmen on the plains make of arbitrary names, monograms or hieroglyphics for indicating what animals belong to this or that particular ranch. And it appears that this view of the meaning of taxonomy and the significance of characters has not wholly died out. The most reasonable explanation of the inordinate species making practised by some botanists is that they are still under

³ "An Essay on Classification," p. 263.

the dominance of the old doctrine of the fixity and inviolability of characters, especially the characters of species. When one holds this view it is very easy for him to find in every variation the indication of a new species, for all one must do is to find that every varietal character is really specific according to such rules as those laid down above by Agassiz. One may logically hold that if characters of a particular kind are of "specific" value, they must be valid, however faint or obscure they may be. Probably the recently observed activity in the making of new species is the flickering of the dying flame of this expiring theory. Wholly inconsistent with the doctrine of evolution, it must soon die out, and we may well be patient while it lasts, praying in the meantime that its final happy extinction may not be long delayed.

I need scarcely refer here to the "map theory" of relationship which was once quite the vogue, and of which remnants are still to be seen in some charts showing the relationships of groups. In some of these we still see an attempt to indicate the genetic relationship of a particular group in more than two directions! Before the general acceptance of the doctrine of evolution such an indication of relationship was quite consistent, for into taxonomy no definite conception of genetic relationship had yet entered. Groups of plants were thought of as related to one another, as we think of the relationship of one state to another on a map. And no doubt it was a helpful device for giving clearer notions of the similarities between plant groups. Just as the children in the schools learned much by the exercise of "bounding" the states, so it was profitable in those ante-evolutionary days to use these imaginary maps to show similarities by nearness or juxtaposition. Yet while the practise may once have been profitable, it is no longer

so, and to engraft genetic ideas upon it is really quite impossible. *

There is still another conception of plant taxonomy to which I must advert, namely, the philosophical division of the vegetable kingdom into convenient groups of various grades, as divisions, subdivisions, classes, subclasses, orders, suborders, etc. Such groups are in a sense natural, in that they are usually characterized by structures which are conceived to have been evolved from others somewhat like them. Yet these have failed to commend themselves permanently, no doubt because generally they have been based upon only one or at best a few closely related characters. Thus the somewhat recent attempt to divide the vegetable kingdom into Protophytes and Metaphytes is an apt illustration, as is also its earlier division into Phanerogams and Cryptogams. And of like nature was the suggestion to divide the dicotyledonous plants into Chalazogamae and Porogamae. The proposal made by Sachs to divide the Thallophytes into Zygosporae, Oosporae and Carposporae, while no doubt it did much to dispel the confusion with regard to the plants included, failed to commend itself generally because it separated clearly related groups of plants. The failure of this arrangement was due not so much to the fact that it was based upon one character—namely, the mode of sexual reproduction—as to the far more important fact that it took practically no account of the evolution of the plants constituting the groups. Herein was its weakness, and in spite of the advantage of clearness and ease of understanding which it possessed to a marked degree, it was never adopted by systematic botanists.

A few columns back I said that a natural classification must be an expression of a theory of evolution. I will go farther now and say that it is sound scientific practise

to change our classification when we change our theory of evolution. This follows logically as a corollary of the main thesis, but it is well to place our acceptance of it on record, lest in our zeal for consistency we may neglect it. No system of classification should stand in its entirety after the theory of evolution upon which it is based has experienced any change whatever. The two must be modified simultaneously, for they are parts of a common system.

What does the theory of evolution involve to-day? It will be well to pause here for a short enumeration of the principal features of this theory so far as they bear upon the question of classification. I need scarcely remind you that for the purposes of this discussion it is not necessary to decide between the different schools of evolutionists, since their differences are almost wholly of such nature as to have little or no bearing upon a system of plant taxonomy.

Elsewhere⁴ I have enumerated the following dicta as involved in the theory of evolution as applied to the vegetable kingdom:

1. In general the lower plants came into existence first.
2. In general the higher plants sprang from the lower.
3. Higher plants are more complex than the lower.
4. Structures with many similar parts (homogeneous) are lower, those with fewer and dissimilar parts (heterogeneous) are higher.
5. Evolution is not always upward, but often involves degradation and degeneration.
6. Evolution does not necessarily involve all organs of the plant equally in any particular period.
7. One organ of a plant may be advancing while another is retrograding.
8. Upward development is sometimes through an increase in complexity, and sometimes by a simplification of an organ or a set of organs.

⁴"A Synopsis of Plant Phyla," *University of Nebraska Studies*, October, 1907, p. 1.

9. In some cases particular structures become more simple while the plants themselves become more complex.

10. Evolution has generally been consistent, and when a particular progression or retrogression has set in it is persisted in to the end of the phylum.

11. Retrogression, once set in, usually persists, and is not followed by a progression.

12. Hysterophytic degeneration is persistent, and the hysterophytic phylum never becomes holophytic.

13. In the first stages in the development of any organ, whether upward or downward, the new structures are not as fixed as they become later, and in these earlier conditions there may be reversions to the ancestral structures, while later such reversions do not occur.

14. All plant relationships are genetic.

15. Plants are related *up and down* the genetic lines, and the system of plants to be quite natural must recognize these phyla.

While these fifteen dicta are by no means all that might be cited, they will suffice for my present purpose. From them the phyletic idea in taxonomy follows logically. Since all natural groups must be phyletic, only that arrangement is natural that recognizes these in their entirety. It should no longer be permissible on scientific grounds to propose a classification which is not phyletic.

We may now profitably inquire as to the origin of phyla, and to seek an answer as far as it is possible to find one in general terms and on theoretic grounds. Stated philosophically, from what we know of the relationship of organic beings it is obvious that a phylum originates with the incoming of a new idea. Stated structurally, it has its beginning with the development of a dominant morphological peculiarity. Stated taxonomically, its initial point is indicated by the appearance of a new character.

Every phylum is the result of a development which differs from that which preceded it because of the incoming of a new dominant idea. This dominant idea was manifested structurally by a divergence

from the previous lines of evolution, and this point of divergence is the actual origin of the new phylum. As far as this idea dominates, so far does the phylum extend, and when a still newer idea comes in and attains dominance, a still newer phylum has its beginning.

In this manner may we mark the beginning and the extent of phyla. They originate with a divergence which is the expression of a new idea. It is what we often call a "tendency." In taxonomy we refer to it as a "new character," this latter term being sometimes somewhat confusingly applied to the underlying idea and sometimes to its obvious structural expression.

The result of the successive development of phyla is quite like that in a tree where newer branches spring from older ones by the formation of buds, from which branches develop in succession. And as there are branches of all grades, from the primitive diverging growths which eventually divide the tree profoundly into great segments, through the smaller and smaller branches to the very recent slender twigs—the growths of but yesterday—so it is with the development of successive phyla from one another, the result being a complex tree-like aggregation with older phyla below and younger and smaller phyla above.

In order to discern phyla, the botanist must certainly be familiar with the whole vegetable kingdom, or at the least with the great region in which the particular phyla under consideration occur. He must be able to bring to mind the families, genera and species of plants with such clearness as will enable him to see the direction of the evolutionary current—the "drift" of evolution in the vegetable kingdom as a whole, and in the particular portion immediately under his consideration. I know that this is often a difficult task, just

as it may be very difficult to determine the direction of the water current in a lake by observations at one point only: yet it may be very easy when the points of observation are multiplied. So it is here difficult, and perhaps impossible, for the man whose point of view is limited to a small portion of the botanical shore-line. The trained eye of the experienced man can catch the drift of the waters from a few properly selected points of observation, and likewise the trained eye of the botanist from observations at properly selected stations may detect the direction of evolutionary progress, as well as the origin and extent of the resulting phyla.

Applying what has been suggested in the foregoing brief and somewhat desultory discussion, it appears to me that we may recognize the following plant phyla of primary rank:

1. *Myxophyceae*, in which the dominant idea is the simple nucleus, typically not limited by a nuclear membrane. The simple plant body, of one or only a few cells, the blue-green diffused pigment, and the soft and often gelatinous walls may be regarded as characters of secondary importance.

Here are included also many hystero-phytes (bacteria) which I regard as degenerates from the normal plants of this phylum.

Probably from the highest *Myxophyceae* came the second phylum—

2. *Protophyceae*, in which the dominant idea is the definite nucleus, limited by a nuclear membrane. The simple plant body of one cell or of a repetition of mostly similar cells, the typically motile, ciliated gametes, the definite chromatophores carrying a chlorophyll-green pigment, and the usually firm cell wall, are limiting secondary characters.

I here include *Pleurococcaceae*, *Ulvaceae*, *Ulotrichaceae*, *Oedogoniaceae*, *Coleocha-*

taceae, and a dozen or so related families. This phylum has been unusually productive of other phyla of primary and secondary rank, and elsewhere⁵ I have hazarded the suggestion that from the lower *Protophyceae* (near *Protococcoideae*) a phyletic line passed off and gave rise to the animal kingdom.

Springing from the filamentous *Protophyceae* is the third phylum—

3. *Zygophyceae*, in which the sluggish cells easily separate, and the non-ciliated gametes move feebly. This is a phylum on the down-grade, and all of its members show structural degeneration. In the desmids and diatoms the filaments usually separate early into single cells, resulting in the so-called "unicellular" structure of these plants.

The filamentous pondscums (*Spirogyraceae*, *Zygnemataceae* and *Mesocarpacae*) are here held to have given rise by early fragmentation to several secondary phyla, including the three families of desmids, and the many families of diatoms.

From the filamentous *Protophyceae* there came also the fourth phylum—

4. *Siphonophyceae*, in which the dominant idea is the development of coenocytes. The retention of the typically motile ciliated gametes producing simple zygotes upon uniting, the chlorophyll-green chromatophores, and the mostly filamentous or upright plant body which is rooted below, are important secondary characters.

Beginning with the segmented *Cladophoraceae* two secondary phyla may be recognized—one (*Vaucherioideae*) of filamentous plants—the other (*Bryopsidoidae*) of upright and branched plants.

⁵ "The Structure and Classification of the Lower Green Algae," in *Trans. Am. Mic. Society*, Vol. XXVI., 1905, pp. 121-136; and later in "A Synopsis of Plant Phyla," 1907. See also my "Essentials of Botany," sixth edition, 1896, pp. 137-8.

Many species have degenerated into hysterophytes.

Again, from the filamentous *Protophyceae* came the fifth phylum—

5. *Phaeophyceae*, in which the dominant feature is the addition of the brown pigment (phycophacin) to the chlorophyll of the cells. The typically motile, ciliated gametes, producing simple zygotes upon uniting, and the filamentous to massive plant body, rooted below, are secondary limiting characters.

Starting with the filamentous and often small *Ectocarpaceae*, this group readily divides itself into two well-marked secondary phyla—*Phaeosporeae*, and *Cyclosporeae*, the former culminating in the gigantic *Laminariaceae*, and the latter in the highly developed *Sargassaceae*.

Going back again to the fertile group of the filamentous *Protophyceae*, we find the origin of the sixth phylum—

6. *Carpophyceae*, whose dominant characters are the reddish pigment (phycoerythrin) added to the chlorophyll of the cells, and the growth of the zygote into a spore-fruit. The mostly erect, symmetrically branched and basally-rooted plant body, and the definite attainment of heterogamy, afford important secondary characters.

Here the typically marine *Bangioideae* and *Florideae* dominate the phylum, and these develop phycoerythrin in their cells, while the green fresh-water *Charoideae* constitute a small side line.

From the more primitive, probably filamentous *Carpophyceae* came the seventh phylum—

7. *Carpomycetaceae*, whose dominant idea is the abandonment of the holophytic habit, and the adoption of the hystero-phytic habit, with the disappearance of chlorophyll, resulting in the atrophy of the vegetative portions of the plant body and the increase in reproductive structures.

The spore-fruit inherited from the preceding phylum undergoes many changes and is often degenerated, and this sometimes involves the gametes themselves.

This phylum is one of marked departure from the general upgrade evolution in the vegetable kingdom, and its successive smaller phyla show increasing degeneration in the structure of the plant body, which in the rusts and smuts becomes excessive, while in some cup-fungi (*Pezizales* and *Helvellales*), puff-balls (*Lycoperdales*) and toadstools (*Hymenomycetales*) the spore fruit is relatively very large.

From the higher *Protophyceae* (probably near *Coleochaetales*) came the eighth phylum—

8. *Bryophyta*, in which the dominant idea is the growth of the zygote into an alternate, short-lived generation, the sporophyte, and the consequent adoption of the land habit.

The two secondary phyla are *Hepaticae* and *Musci*.

From the lower *Bryophyta* (probably near *Anthocerotales*) came the ninth phylum—

9. *Pteridophyta*, whose dominant character is the growth of massive roots and broad leaves upon the sporophyte, rendering it long-lived and independent, and resulting in the postponement of spore formation.

It must be noted here that I use the term *Pteridophyta* in the narrower sense, limiting it to ferns (*Filicinae*) and excluding lycopods and horsetails. The incoming of heterospory in some ferns is a significant fact.

From the lower *Pteridophyta* (probably near *Ophioglossales*) came the tenth phylum—

10. *Lepidophyta*, in which the dominant character is the long-lived, erect cylindrical stem of the sporophyte, which bears massive roots below, is covered with many

small scattered leaves, and terminates in a strobilus of imbricated sporophylls above.

From the lower *Pteridophyta* again (probably near *Ophioglossales*) came the eleventh phylum—

11. *Calamophyta*, in which the dominant character is the long-lived, erect, cylindrical stem of the sporophyte, which bears massive roots below, regularly whorled leaves and branches, and terminates in a strobilus of whorled sporophylls.

In the two preceding phyla, heterospory, although present, has not yet become fixed. In both the increased definiteness of the strobilus is significant.

From other lower *Pteridophyta* (near *Marattiales* of *Isoetales*) came the twelfth phylum—

12. *Cycadophyta*, in which the dominant idea is the uniform production of heterospores in simple strobili of open sporophylls, upon the megaphyllous, spongy-wooded sporophyte, and the permanent retention of the megaspore in the sporangium, thus forming the seed.

I here include not only the cycads proper (*Cycadineae*), but also the much more primitive "seed ferns" (*Cycadofilices*), the ancestral conifers (*Cordaitineae*), the ancestral flowering plants (*Bennettitineae*), and the maiden-hair trees (*Ginkgoineae*).

From *Cycadophyta* came the—

13. *Gnetales*, if indeed they are not to be regarded as belonging to that phylum.

The three genera are doubtless the surviving remnants of former rather well developed secondary phyla, now nearly extinct.*

From the *Cycadophyta* came the fourteenth phylum—

14. *Strobilophyta*, in which the dominant idea is the development of definite,

* Consult here Arber and Parkin's paper on the *Gnetales*, in *Annals of Botany*, Vol. XXI. (1908), p. 489.

compact strobili of open microsporophylls and megasporophylls upon the microphyllous, solid-woody sporophyte.

I regard the cone-bearers proper—*Taxodiaceae*, *Araucariaceae*, *Abietaceae*, *Cupressaceae*, etc., as more primitive, and that from these have sprung such specialized forms as *Podocarpaceae*, *Phyllocladaceae* and *Taxaceae*.

From the *Cycadophyta* came also the fifteenth phylum—

15. *Anthophyta*, in which the dominant idea is the closure of the megasporophyll, and the transformation of the plain strobilus into the ornamental flower.

I am very glad to be able to suggest the restoration of the wholly appropriate name—*Anthophyta*—for this phylum. As I conceive this immense group, it is rather sharply divided into three secondary phyla which diverge from a common point of beginning—the so-called “Ranalian plexus.” Two of these secondary phyla are dicotyledonous, while the third is monocotyledonous. The first culminates in the mints (*Lamiales*), the second in the sun-flowers (*Asterales*) and the third in the orchids (*Orchidales*).

With regard to the relationship of the four phyla last named many facts have been brought to light during the past few years, which have quite materially modified the generally prevailing theories. With the publication of Wieland's epoch-making book on American cycads⁷ attention has been centered upon the primitive cycads as the group of gymnosperms from which the angiosperms must have sprung. It is no longer a tenable hypothesis that the conifers are allied to the Amentiferae, as has long been held by many botanists. It is no longer necessary to begin the phylogeny of angiosperms with apetalous forms so as to make easier the passage

from Coniferae. In fact, for many years there have been those who held that apetalous plants are not primitive, but on the contrary have been derived from petalous forms by reduction. Sixty years ago or more Jussieu hinted at the real nature of apetalous plants⁸ and suggested the primitive nature of the Ranales, and consistently placed the Compositae at the summit of his system.

In the vice-presidential address⁹ which I had the honor of delivering before this section fifteen years ago, after a careful examination of the families in the so-called Apetalae the conclusion was reached that “when we search for families in the Apetalae which may satisfy the requirements of a primitive group from which the dicotyledons may have evolved, we find none which will serve our purpose.” Following the hint of Jussieu, the attempt was made to distribute the apetalous families among polypetalous and gamopetalous orders. A revision of the monocotyledonous and dicotyledonous orders was made so as to bring the apocarpous families near the beginning (lowest) point. Thus the water-plantains (*Alismales*) were given the first (lowest) place among monocotyledons, and buttercups (*Ranales*) and roses (*Rosales*) similar places among dicotyledons. From the water plantains (*Alismales*) a phyletic line was traced through the lilies (*Liliales*) to the modified (simplified) calla lilies (*Aroidales*), palms (*Palmiales*) and grasses (*Graminales*), which form lateral offshoots of the main line, and then onward from lilies (*Liliales*) through irises (*Iridales*) to orchids (*Orchidales*). In like manner a phyletic line was traced from buttercups (*Ranales*) to pinks (*Caryophyllales*), prim-

⁷ “American Fossil Cycads,” by G. R. Wieland, 1906.

roses (*Primulales*), phloxes (*Polemoniales*) to figworts (*Personales*) and mints (*Lami-ales*). Another line was sketched from roses (*Rosales*) to umbelworts (*Umbell-ales*), madders (*Rubiales*) and sunflowers (*Asterales*). Certain details of that arrangement, as the disposition of *Celastrales* and *Sapindales*, and the retention of the *Choripetalae* and *Gamopetalae* as valid groups, were subsequently found to be erroneous, and were corrected, but in the main the system as then outlined has been sustained by subsequent careful studies of the families.

Two years later¹⁰ this general arrangement was expanded so as to include brief characterizations of the orders, suborders and families, and in it the *Celastrales* and *Sapindales* were brought into the phyletic line extending from *Rosales* to *Asterales*, but the *Choripetalae* and *Gamopetalae* were still recognized as valid groups.

A year later, in an elementary textbook¹¹ the *Choripetalae* and *Gamopetalae* were abandoned as definite groups of angiospermous orders, since it is evident that gamopetaly has been attained independently in at least two phyletic lines.

In my presidential address¹² before the Botanical Society of America in 1897, the dicotyledons were arranged in "two somewhat diverging genetic lines or phyla, each beginning with apocarpous, hypogynous, choripetalous plants, and both attaining syncarpy and gamopetaly, one remaining hypogynous, the other becoming epigynous." A little later it is explained that "since gamopetaly has evidently been attained at more than one point, it is no

longer desirable to retain the *Gamopetalae* as a distinct group."

The latest restatement of this arrangement of the flowering plants was published at the beginning of the present year in my "Synopsis of Plant Phyla,"¹³ already referred to earlier in this address. In it many minor corrections were made, and some suggestions were hazarded as to the point of origin of angiosperms, and conifers. These suggestions followed the line sketched by Arber and Parkin in their paper on the "Origin of Angiosperms"¹⁴ published a few months earlier. Basing their argument upon the discoveries of Wieland¹⁵ these authors concluded that angiosperms were derived from Cycadean ancestors of the Bennettitean type, with an open flower-like strobilus ("pro-anthostrobilus") of megasporophylls, microsporophylls ("amphisporangiate") and asporophylls ("perianth"). As a consequence they arrive at the conclusion that primitive angiosperms were necessarily polypetalous, hypogynous and apocarpous, precisely the conclusion reached by me on theoretical grounds more than fifteen years ago, and since then persistently held in the face of the increasing popularity of Engler's system. It would now appear probable that there must soon be another rearrangement of the flowering plants. We have recently witnessed the almost complete inversion of the sequence of the families of flowering plants in our systematic manuals, and it appears now that we shall barely have time to become accustomed to the new order before we shall have to learn still another. It seems now inevitable that such orders as

the buttercups (*Ranales*), water plantains (*Alismales*), and roses (*Rosales*) are to be regarded as primitive, and as a consequence they must stand at the beginning of the great phylum *Anthophyta*, as also each must stand at the beginning of its smaller phylum. That the phylum beginning with the water plantains (*Alismales*) must find its highest development in the irises (*Iridales*) and orchids (*Orchidales*) can not be doubted; nor can it be questioned that grasses (*Graminales*), calla lilies (*Aroidales*) and palms (*Palmales*) must now stand as reduced from the type of the lilies (*Liliales*). This leaves no room for radical differences of opinion, and in fact little room for any but the most minor differences in regard to the proper sequence of the monocotyledonous families.

In like manner beginning with the Ranzanian type in the dicotyledons, it is obvious that one phyletic line culminates in the gamopetalous, bicarpellate, hypogynous order of the mints (*Lamiales*), while another passes through the roses (*Rosales*) (if indeed they are not themselves primitive), and umbelworts (*Umbellales*) to the sunflowers (*Asterales*). Here again, with regard to the details as to the intermediate orders there may be much difference of opinion. Yet there will be no question that in one line the pinks (*Caryophyllales*) and mallows (*Malvales*) are lower than primroses (*Primulales*) and heaths (*Ericales*), nor that the latter are lower than phloxes (*Polemoniales*) and mints (*Lamiales*). In the other line the myrtles (*Myrtales*) are clearly lower than umbelworts (*Umbellales*), while the latter are manifestly lower than madders (*Rubiales*), and these than sunflowers (*Asterales*). In fact when we agree to the hypothesis that polypetalous, hypogynous, apocarpous flowers are primitive the great outlines of the phylum (or phyla) are quite obvious, and the only ques-

tionable points are with reference to the place and sequence of intermediate orders. And it is here that much critical work invites the close attention of taxonomists. The great outlines—the boundaries of the phyla—are drawn, but the particular manner in which many of the interior families are related to each other has not yet been made out.

The principles here brought forward, and the general plan which I have so hastily sketched, have been so serviceable in the presentation of the subject of taxonomy in my lectures to university students that I venture to lay them before you as a general working hypothesis. My own success in its use encourages me in the hope that in the hands of others it may be equally helpful in enabling the student of taxonomy to more clearly apprehend the mode of evolution in the vegetable kingdom, and the consequent relationship of the resulting multiplicity of types.

CHARLES E. BESSEY

THE UNIVERSITY OF NEBRASKA

THE DARWIN CENTENARY AT CAMBRIDGE

SOME details are given in the London *Times* of the celebration by the University of Cambridge of the centenary of the birth of Charles Darwin and the jubilee of the first publication of "The Origin of Species." It is expected that delegates selected by universities, academies, colleges and learned societies will arrive in Cambridge on Tuesday, June 22, and that the arrangements for their entertainment, which are, however, subject to alteration, will be as follows: On the evening of the twenty-second there will be a reception, probably in the Fitzwilliam Museum, by the chancellor. On Wednesday, June 23, addresses will be presented by the delegates to the university in the senate house. It is hoped to present to each delegate a copy of the first draft of "The Origin of Species." In the afternoon there will be a garden party at Christ's College, where Darwin was a stu-

dent, and in the evening the university will give a banquet. On Thursday, June 24, the Rede lecture will be delivered, and honorary degrees will be conferred. It is further proposed to hold an exhibition of portraits, editions and relics of Darwin at Christ's College, somewhat similar to the Milton exhibition of last June.

Already some 200 delegates have been appointed to represent institutions, including:

Professor W. G. Farlow, American Academy of Arts and Sciences, Boston; Professor C. S. Minot, Boston; Professor R. H. Chittenden, Yale University, New Haven; Professor E. B. Wilson, Columbia University, New York; Dr. J. M. Baldwin, Johns Hopkins University, Baltimore; Professor J. Loeb, University of California, Berkeley; Dr. H. F. Osborn, American Philosophical Society; Dr. L. O. Howard, Academy of Sciences, Washington; Mr. C. F. Cox, Academy of Sciences, New York; Domingo Gana, Universidad de Chile, Santiago; Hofrat Dr. L. von Graff, Gratz; Professor Vojdovsky, Prague; Hofrat Dr. F. Steindachner, Vienna; Professor E. van Beneden, Brussels; Professor H. F. E. Jungersen, Copenhagen; Professor Cuénot, Nancy; M. van Tieghem, Institute de France, Paris; Le Prince Roland Bonaparte, Institute de France, Paris; Professor E. Metchnikoff, Pasteur Institute, Paris; Ober-Regierungsrat Professor Adolf Engler, Deutsche Botanische Gesellschaft, Berlin; Dr. F. von Luethen, Gesellschaft für Anthropologie, Ethnologie und Urgeschichte, Berlin; Professor Kukenthal, Breslau; Professor Max Verworn, Göttingen; Professor Bütschli, Heidelberg; Professor R. Hertwig, Munich; Professor Goebel, Munich; Professor E. Ballowitz, Münster; Professor Graf zu Solms-Laubach, Strassburg; Professor Th. Boveri, Würzburg; Professor H. de Vries, Amsterdam; Professor J. H. van Bemmelen, Groningen; Professor A. A. W. Hubrecht, Utrecht; the Italian Ambassador, Marquis of San Giuliano, Società Geografica Italiana, Rome; Professor C. Ishikawa, Tokio; Dr. W. C. Brögger, Christiania; Professor V. M. Simkevich and Professor V. V. Zilenskiy, St. Petersburg; Professor H. Théel, Professor Chr. Aurivillius and Professor A. G. Nathorst, Stockholm; Dr. Paul Sarasin, Zurich; the Right Hon. Sir John Buchanan, University of Cape of Good Hope, Cape Town; Sir Richard Solomon, University College, Johannesburg; Professor A. Liversidge, Royal Society of New South Wales, Sydney; Sir E. T. Candy, the University, Bombay; Sir Lewis

Tupper, Panjab University, Lahore; Dr. J. C. Willis, Royal Botanic Gardens, Peradeniya; Professor E. Rutherford, Christchurch, New Zealand; Sir Oliver Lodge, Birmingham University; Sir Isambard Owen, Durham University; Dr. A. W. W. Dale, Liverpool University; Sir Archibald Geikie, the Royal Society, London; Lord Avebury, Sir T. Lauder Brunton and Sir E. Ray Lankester, the Royal Society, London; Mr. Francis Darwin, British Association for the Advancement of Science; the Duke of Northumberland, the Royal Institution, London; Sir James Crichton-Browne, the Royal Anthropological Institute, London; Lieutenant-Colonel D. Prain, Royal Botanic Gardens, Kew; Professor G. C. Bourne, Dr. F. Gotch and Professor E. B. Poulton, Oxford University; Sir Charles Eliot, Sheffield University; Mr. R. F. Scharff, Royal Zoological Society, Dublin; Professor W. C. McIntosh, St. Andrews University; Sir William Turner and Professor Cossar Ewart, Edinburgh University; Principal E. H. Griffiths, University College, Cardiff.

WOLCOTT GIBBS

THE death of Wolcott Gibbs takes a commanding figure from the ranks of the veterans of science. Attaining the age of over eighty-six years, he had been for a long time almost the sole survivor among the pioneers of American chemistry. He was one of the founders of the National Academy of Sciences in 1870; and he alone saw his name included among those of living members in 1908.

For over a decade he had headed in academic seniority the list of the faculties of Harvard University. He served there as Rumford professor for twenty-four years, and in honorable retirement bore the title of Rumford professor emeritus for twenty-one years more. The infirmity due to his increasing years had withdrawn from him the privilege of contributing to the growth of his beloved science; but his interest in the work of others remained keen and enthusiastic until the end had almost come—until pain had driven away all the joy of life.

It has been said that he was one of the pioneers of American chemistry. He was made assistant professor in New York at the age of twenty-six in 1848. His eager and energetic spirit and his thorough training

under the inspiring guidance of Rose, Rammeisberg, Liebig, Laurent, Dumas and Regnault had given him an insight into the possible future of chemistry which forbade his contentedly settling down into the mere routine of teaching. Thus at once he joined the then pitifully small band of Americans who sought to advance the bounds of knowledge.

It is impossible here to present a detailed survey of the greatly varied fields in which his work lay, but a brief sketch will give some idea of the activity of his scientific imagination. His first important research concerned the complex ammonia-cobalt compounds, one of the most interesting series among inorganic substances. This masterly work, conducted with the collaboration of F. A. Genth, shed much light upon the puzzling nature of complex compounds in general, and laid the foundation for one of the most elaborate of modern chemical theories. The following years (1861-4) saw him engaged upon a careful study of the platinum metals, upon which he was engaged when he accepted the call to Cambridge in 1863. Shortly afterward (1864) he published for the first time a description of his use of the voltaic current for depositing copper and nickel in such a manner that the deposited metals could be directly weighed—thus providing a simple and exact quantitative method for the analysis of substances containing these metals. The fact that a German, Luckow, afterwards stated that he had used the method for copper before Gibbs had used it, does not detract from the real originality of Gibbs's idea; for Luckow's work was wholly unknown to Gibbs.

From time to time throughout all Gibbs's long period of scientific activity there appeared papers from his pen describing other new and useful methods of quantitative analysis, many of which have been incorporated into the common analytical practise of to-day. For example, his sand-filtering device of 1867 may be said to have been a forerunner of the present admirable apparatus perfected by Gooch and Munroe.

Not long after coming to Harvard, Gibbs

turned his attention to the precise use of the spectrometer in chemical investigation, and this work was continued in 1875. Throughout all this time the subject of his work with Genth was only half dormant in his mind, and occasional theoretical or experimental papers concerning the peculiar nature of cobaltamine compounds showed his devotion to his early choice.

Not content with the paradoxes and puzzles offered by these complex bases, or with the other abstruse subjects mentioned, he attacked in succeeding years the complex inorganic acids, composed of various combinations of tungstic, molybdic, phosphoric, arsenic, antimonie and vanadic acids. One can not help wishing, upon studying his patient and careful quest among the bewildering phenomena manifested by these singular substances, that he had had the assistance of modern physical chemistry. But our present knowledge was not then at any one's disposal, and Gibbs did his best with the means at his command, devoting himself for a number of years to the expansion and systematizing of the work in this but slightly cultivated field.

From inorganic chemistry he later turned for a short time to a very different subject, undertaking with H. A. Hare and E. T. Reichert, a systematic study of the action of definitely related chemical compounds upon animals. This research, which appeared in 1891 and 1892, together with occasional previous papers upon organic chemistry, afforded evidence of the breadth of his interest.

Keen as his sense of the importance of physiological chemistry became, it was not keen enough to divert him wholly from his devotion to the rarer substances of the inorganic world, as his following paper on the oxides contained in cerite, samarskite, gadolinite and fergusonite testified.

Although Wolcott Gibbs was essentially an experimentalist, he was one of the first of American chemists to appreciate the importance of thermodynamics. His large library contained all the standard works upon heat, and his influence was the prime factor in having caused the award of the Rumford

medal to J. Willard Gibbs as early as 1880, long before the world at large appreciated the fundamental character of the work of the great New Haven physicist. Wolcott Gibbs served on the Rumford Committee of the American Academy for thirty years (1864-94), and in many other ways did his best to aid the progress of science in America. He was for a time president of the National Academy of Sciences, until ill health enforced his resignation; and he served also as president of the American Association for the Advancement of Science.

Not only at home, but also abroad, his eminence was worthily recognized. His election to honorary membership in the German Chemical Society in 1883 and, to corresponding membership in the Royal Prussian Academy in 1885 is perhaps the most striking evidence of the foreign appreciation of his work. No other American chemist has ever attained to either of these high honors.

The brief autobiography published in the issue of SCIENCE for Friday, December 18, makes unnecessary a repetition of the chief events in his quiet daily life. His manhood was spent partly in New York, partly in Cambridge, and finally during recent years, among his cherished flowers at his home on Gibbs Avenue near the First Beach at Newport, R. I. The circumstances of his early academic life brought him into close contact with but few students. This is the more to be regretted because his enthusiastic spirit, his tireless energy, his generous recognition of everything good, and best of all his warm human friendship endeared him to all who knew him. Those who were thus fortunate, whether students or colleagues, will always devotedly treasure his memory; and his place as a pioneer of science in America will always be secure.

THEODORE WILLIAM RICHARDS

SCIENTIFIC NOTES AND NEWS

THE honorary local secretaries of the British Association for the Advancement of Science to be held in Winnipeg from August 25 to September 1, of the present year, are O. M. Bell, Esq., W. Sanford Evans, Esq., Professor

M. A. Parker. Enquiries and communications on matters connected with the meeting should be addressed: To the Local Secretaries, British Association for the Advancement of Science, University Building, Winnipeg, Man.

THE American Society of Zoologists, Eastern Branch, at its recent meeting in Baltimore, elected the following officers: *President*, Professor Herbert S. Jennings, the Johns Hopkins University; *Vice-president*, Professor H. V. Wilson, University of North Carolina; *Secretary-treasurer*, Dr. Lorande Loss Woodruff, Yale University; *Member of Executive Committee*, Professor Maynard M. Metcalf, Oberlin College.

A DIVISION of Food and Agricultural Chemistry of the American Chemical Society has organized and elected the following officers and executive committee: *Chairman*, W. D. Bigelow; *Vice-chairman*, C. A. Brown; *Secretary*, W. B. D. Penniman; *Executive Committee*, F. K. Cameron, H. H. Huston, P. Rudnich, B. E. Curry.

At the annual meeting of the Academy of Science of St. Louis, Professor Trelease was elected president, and Professor McCourt, recording secretary, for the current year.

PRESIDENT JAMES B. ANGELL, of the University of Michigan, celebrated his eightieth birthday on January 7, while attending the meeting of the Association of American Universities, at Cornell University.

PRESIDENT ELIOT, of Harvard University, expects to leave Cambridge on February 7, for a two-months' trip through the middle west to the southwest and south, during which he will make a large number of addresses to Harvard alumni and others.

DR. ALBRECHT PENCK, professor of geography at Berlin, and this year Kaiser Wilhelm professor at Columbia University, has been given the degree of doctor of science by Columbia University.

THE Wahlburg gold medal of the Swedish Society for Anthropology and Geography will be presented to Dr. Sven Hedin on his return to Stockholm. This is the second

presentation of the medal, it having been given previously to Professor G. Retzius.

PROFESSOR THEODORE W. RICHARDS has received a seventh grant of \$2,500, and Assistant Professor Gregory P. Baxter a fifth grant of \$1,000, from the Carnegie Institution of Washington, to aid in researches upon physico-chemical constants.

MR. E. R. LLOYD, Rhodes scholar at Oxford from West Virginia, who was placed in the first class in the final honor schools, has been awarded the Burdett-Coutts scholarship in geology, which is held for two years and is of the annual value of £115.

KING EDWARD has appointed Dr. H. R. D. Spitta to be bacteriologist to his household.

MR. RAPHAEL ZON, who will have charge of the forest experiment station work in the re-organized Forest Service, is now abroad studying the stations in Europe.

MR. C. A. McLENDON has resigned the position of assistant botanist and plant pathologist at the South Carolina Experiment Station to accept the position of botanist and plant pathologist at the Georgia Experiment Station, Experiment. He takes the place recently vacated by the removal to the State College, at Athens, of Professor R. J. H. De Loach.

It is announced that Professor George Hempl, of Stanford University, has made important discoveries in the interpretation of inscriptions left by the Etruscans.

PROFESSOR S. A. MITCHELL, of Columbia University, on successive Saturday evenings, beginning January 9, delivers a course of lectures on "Astronomy" at the Wagner Institute, Philadelphia, as follows: (1) The sun and its motion through space; (2) Eclipses of the sun; (3) Wonders of the heavens revealed by the spectroscope; (4) Foucault's pendulum; (5) The moon; (6) Is Mars inhabited?

THE Southern California Science Association was organized at Occidental College, Los Angeles, Cal., on December 12. The next meeting will be held in April at the University of Southern California, Los Angeles. The following officers were elected at the meeting for organization: *President*, W. A. Fiske,

Occidental College, Los Angeles; *Vice-president*, W. R. Bowker, University of Southern California, Los Angeles; *Secretary-treasurer*, H. T. Clifton, Throop Polytechnic Institute, Pasadena.

At the meeting of the Middletown Scientific Association, on January 12, Charles Edward Amory Winslow, assistant professor of sanitary biology at the Massachusetts Institute of Technology, gave an illustrated lecture on "Water Supply and Water Purification."

DR. JOHN A. BRASHEAR lectured at Lehigh University on December 11 on contributions of photography to our knowledge of the stellar universe.

THE agricultural faculty and experiment station staff of Clemson College, S. C., have formed an organization to be known as the Clemson Biological Club. Dr. C. H. Shattuck has been elected president and Professor A. F. Conradi, secretary. Regular meetings will be held each week.

THE British Admiralty will restore Halley's grave in the old burial-ground of Lee Parish Church. E. Halley, who was the astronomer royal from 1721 to 1742, was given the temporary rank of a captain in the navy, and commanded a ship of war in 1698-1701, for the purpose of making observations for magnetic variations.

A COMMITTEE has been formed in Denmark to erect a memorial to Mylius Erichsen, who perished with his companions while engaged in explorations in Greenland. It is expected that the memorial will take the form of a lighthouse to be erected on the Danish coast.

A MONUMENT to Professor von Krafft-Ebing, was unveiled in the hall of the University of Vienna at the time of the recent international congress in that city on the care of the insane.

It is proposed to erect a building for surgical cases in connection with the Presbyterian Hospital, New York, as a memorial to the late Dr. Andrew J. McCosh. The chairman of the committee having charge of the memorial is Mr. John S. Kennedy, New York City.

THE Brooklyn Institute of Arts and Sciences held a Charles Darwin centennial meet-

ing on the evening of January 12, when an address on "Charles Darwin and his Influence" was made by Professor Edward G. Poulton, of Oxford University.

As we have already announced, arrangements have been made for the celebration of the one-hundredth anniversary of the birth of Charles Darwin by the New York Academy of Sciences on February 12 at the American Museum of Natural History. In addition to the presentation to the museum of a bust of Darwin—the presentation to be made by Charles F. Cox, president of the academy, and the acceptance by Henry F. Osborn, president of the museum—addresses will be made on "Darwin's work in botany," by Professor N. L. Britton; on "Darwin's work in zoology," by Professor H. C. Bumpus; and on "Darwin's work in geology," by Professor J. J. Stevenson.

DR. GEORGE GORE, F.R.S., formerly lecturer on chemical and physical science at King Edward's School, Birmingham, the author of works on electrometallurgy and other subjects, has died at the age of eighty-two years.

A RECENT communication from Vienna announces the death, after a long and painful illness, of the eminent Austrian physicist and meteorologist, Hofrat Professor Dr. Josef Maria Pernter on December 20, 1908, at Arco, Tyrol, Austria. Professor Pernter was the director of the Austrian Central Institution for Meteorology and Geodynamics, Hohe Warte, Vienna, a member of the International Meteorological Committee and vice-president of the Austrian Meteorological Society. His death at the comparatively early age of sixty may leave still incomplete his important "Treatise on Meteorological Optics."

WE learn from the *Journal* of the American Medical Association that the recent small epidemic of yellow fever at Saint-Nazaire, on the French coast, has impressed on the authorities the necessity for more effectual measures against yellow fever in the French colonies, whence the disease was imported. The task was entrusted to Drs. Simond and Marchoux, who spent some time in Brazil two or three years ago in study of tropical dis-

eases. They left for Martinique November 11, fully equipped for the extermination of yellow fever and malaria mosquitoes in Martinique and Guadeloupe.

THE appropriation bill in which are included the appropriations for carrying on the work of the Bureau of Education has passed the House of Representatives and is now in the Senate Committee on Appropriations. The only increase over appropriations for the previous year made by the House of Representatives is provision for an editor at two thousand dollars per annum. The bureau needs badly provision for larger and more sanitary quarters than it now occupies, a considerable increase in its staff, as well as an increase in the salaries of the present members of the staff, and is endeavoring to secure these increases in the Senate.

A BULLETIN from the Harvard College Observatory, under date of January 5, states that the variable star, 154428, R Coronæ was found by Mr. Leon Campbell to be faint on January 1, 1909, magn. 8.2. This star is usually of the magnitude 6.0, but occasionally undergoes marked and apparently irregular diminutions in light, sometimes becoming as faint as magnitude 13. The last diminution in brightness lasted from February 8 to September 6, 1905. On November 12, 1908, its magnitude was 6.1, and on December 13, 1908, it was 6.9. Only two other stars of this class have been as yet discovered, 191033, R J Sagittarii and 054319—Tauri, the latter being now exceedingly faint. All three of these stars are being followed closely, both photographically and visually.

THE *American Museum Journal* states that through Edward L. Dufoureq, the directors of the Minas Pedrazzini Company at Arizpe, Sonora, Mexico, have presented to the mineral cabinet a remarkable specimen of crystallized polybasite. This ore of silver (sulphantimonide of silver with some of the silver replaced by copper) furnishes a large part of the vein material from which the silver is obtained in this mine. At favorable points there have developed beautifully crystallized specimens of the mineral upon a scale of magnitude almost

unique. The entire mass as forwarded consisted of a crystallized surface, displaying small and large crystals, nestling upon an ore body of considerable size. The value in bullion of this aggregate was \$640, and it probably was the largest mass of polybasite ever taken from a mine entire.

THE growth of the mineral industries of the United States is graphically exhibited by a chart just issued by the Geological Survey, tabulating for each year of the last decade the quantity and value of the output of our metallic and non-metallic mineral products. This chart shows that in 1898 the domestic production of the metals—pig iron, silver, gold, copper, lead, zinc, quicksilver, aluminum, antimony, nickel and platinum—had a total value of \$305,482,183; in the same year the total value of the other mineral products amounted to \$418,790,671; the grand total for the country in 1898 was therefore \$724,272,854. Ten years later, at the close of the calendar year 1907, the value of the metals had increased to \$903,024,005, that of the other products to \$1,166,265,191, and the grand total was \$2,069,289,196. The chart has interest in connection with a summary of the mineral production of the country, published by the survey as an advance chapter from "Mineral Resources of the United States, Calendar Year 1907," and copies of both the chart and the summary may be obtained by applying to the director of the survey at Washington, D. C. The survey has also published for free distribution separate chapters of its annual report on the mineral resources of the country, giving detailed statistics of many of the products that make up these totals.

Nature states that the council of the Röntgen Society has decided to act upon the advice of the committee appointed in 1906 to consider the possibility of preparing a standard for the measurement of radioactivity. This committee recommends that "The γ -ray ionization from 1 mg. of pure radium be regarded as a standard, and called a unit of radioactivity." The council has deputed Mr. C. E. S. Phillips to prepare a set of three substandards of RaBr₂, and these are now maturing.

By the cooperation of Professor E. Rutherford, comparison will be made with a specimen of the purest RaBr₂, at the Victoria University, Manchester. The quantity of radium in other specimens will be capable of accurate measurement by comparison with the substandards. It is anticipated, therefore, that by this means the exact description of medical, physical or other work with radium will be facilitated, and that the possibility of fraud in the sale of expensive radium preparations will be eliminated. The council proposes to lend the substandards to any competent person desiring to measure the amount of radium in his possession, or to arrange for authoritative tests to be made. For further particulars application should be sent to the honorary secretary of the Röntgen Society, at 20 Hanover Square, London, W.

THE following, as we learn from the *British Medical Journal*, are among the prizes awarded by the Paris Académie de Médecine for 1908: The Laborde prize (£200) for the most notable advancement of surgery, has been given to Professor Monprofit, of Angers, for his work on the operative surgery of the stomach; the Theodore Herpin prize (£120) has been gained by Dr. Albert Deschamps, of Riom, for an essay on the diseases of energy—general asthenias; the Amussat prize (£40) has been awarded to Dr. Destot, of Lyons, for a radiographic and clinical study.

UNIVERSITY AND EDUCATIONAL NEWS

IOWA COLLEGE has obtained an additional endowment of \$500,000, of which \$100,000 is from the general education board and \$50,000 from Mr. Andrew Carnegie.

MR. JOHN W. GATES has given \$100,000 to establish a college at Port Arthur, Texas.

MR. JACOB H. SCHIFF, of New York City, has given \$100,000 towards the construction of a Jewish institute of technology at Haifa, Palestine.

WE learn from the London *Times* that the foundations of the laboratory which is being given to the University of Oxford for electrical work by the Drapers' Company are now being constructed. The laboratory will measure

about 104 feet by 92 feet by 51 feet high, and will be built of red brick and stone. It will be situated in the Parks close to the other buildings devoted to science, which are grouped around the museum. The ground floor will contain a class-room 50 feet by 27 feet, a workshop of about the same dimensions, as well as research, battery and dark rooms. On the first floor provision is made for a lecture-hall 36 feet square and two class-rooms over 50 feet long, while on the second floor there will be a class-room about 100 feet long, besides large lecture and research rooms.

THE President of the United States has instructed the Commissioner of Education to aid in all appropriate ways within his power in the carrying out of the plans of the Chinese Government for the education of students in America. The Chinese Government purposes sending 100 students to America every year for four years, and a minimum of 50 students every year thereafter during the period of the cancelled indemnity payments by China to the United States, from 1909 to 1940.

PROFESSOR DONALD J. COWLING, of Baker University, Baldwin, Kas., was elected president of Carleton College, Northfield, Minn., to succeed the Rev. R. H. Sallmon.

MR. W. H. EMMONS, of the U. S. Geological Survey, is giving courses on petrography and economic geology at the University of Chicago.

DR. A. J. GROUT has been appointed first assistant in biology in the Curtis High School, New Brighton, Staten Island.

DR. ARNOLD LANG, of Zurich, has declined the call to Jena as the successor of Professor Haeckel.

PROFESSOR PFLÜGER, of Breslau, has been called to Berlin as director of the Institute of Hygiene in the place of Professor Rubner who has been transferred to the chair of physiology.

DISCUSSION AND CORRESPONDENCE *

A DISCLAIMER

HARDLY had the experimental researches at the Nutrition Laboratory of the Carnegie In-

stitution of Washington, located in Boston, been established when the scientific staff were besieged by innumerable newspaper reporters seeking information whereon they could base sensational articles for distribution in the public press. Much to my regret, a lengthy article was distributed broadcast throughout the American press on December 20, purporting to describe the Nutrition Laboratory, the experiments made therein, and the plans for the future. It is needless to say that the whole article was prepared without my knowledge and has left an entirely erroneous impression with regard to the work of this institution.

Briefly, the researches now being carried out in Boston were instituted by Professor Atwater, at Wesleyan University, some fifteen years ago. After Professor Atwater's untimely retirement, I had charge of the researches at Wesleyan University and since then they have been transferred to Boston to a special laboratory. The apparatus used at Wesleyan University has been described in detail in Publication No. 42 of the Carnegie Institution of Washington and a discussion of a series of experiments with it made on man during inanition was reported in Publication No. 77 of the institution. The forthcoming "Year-book of the Carnegie Institution" contains a short statement of the laboratory, the plan, and general information regarding it. The newer calorimeters have not been described as yet. All results of experiments made in this laboratory will be published in regularly accredited scientific journals and in the reports published by the Carnegie Institution of Washington. It has been my policy not to publish original scientific material in popular scientific or semi-scientific magazines, much less would I use the daily newspaper as a vehicle for presenting this material to the scientific public.

In connection with the last newspaper announcement regarding this laboratory, there is a very unfortunate statement that as a result of experiments thus far made in the laboratory, the treatment of diabetes would be materially modified and improved, thus holding out hope to the large number afflicted with this

disease that a speedy recovery might be expected. Indeed, I have already begun to receive letters from these unfortunate diabetics who have thus had their hopes falsely raised.

THE LATE PROFESSOR PACKARD'S "GUIDE TO THE STUDY OF INSECTS"

My father, Professor Alpheus Spring Packard, had purposed to rewrite and bring the "Guide to the Study of Insects" up to date, as soon as he had finished Part II. of his "Monograph of Bombycine Moths," which was going through the press at the time of his death. He left many notes and references in regard to the "Guide," which we had intended to use as a preface, but we find they can not be edited properly by another hand.

QUOTATIONS

THE ADMINISTRATION AT THE UNIVERSITY OF ILLINOIS

THE University of Illinois has been coming to the front in the last few years more rapidly than any of the other state universities. It now ranks eighth among the great universities of the United States in the number of students, and is receiving large appropriations from the legislature, for the people of Illinois are determined that their own institution shall not be surpassed by any within the state, especially one founded by John D. Rockefeller. More important than its growth is the raising of the standard of scholarship, the introduction of new men of ability and promise, and the opening of a graduate school. This rapid progress is to be credited chiefly to the energy and initiative of President Edmund J. James, who left Northwestern four years ago to take charge of the state university.

But the University of Illinois is suffering somewhat from the twinges of growing pains. Such a radical and rapid transformation can not be effected without hurting the feelings of

some one or several. One such, Dr. George T. Kemp, has made his grievance a public question by his articles in the local papers and in SCIENCE of October 9, charging President James with duplicity, dishonesty and abuse of official powers. Dr. Kemp does not ask for sympathy on personal grounds. If his manner of leaving the university has impaired his chances of getting a position in another college, he can fall back on his profession, and make more money by the practise of medicine. But he holds that the question of academic freedom *versus* presidential tyranny is involved in his case, and it is therefore of public importance.

The essential facts seem to be as follows: When the graduate school was established a year ago, certain departments were selected for development, as it was impossible to bring them all at once to this rank. Professor Kemp was not one of the professors promoted, his salary was not raised to the prevailing rate, and his department did not share in the general prosperity. He felt, doubtless rightly, that this indicated that he was not in favor with the administration, and, being a high-spirited man, he resented it as a slight upon his honor and ability. He forced the issue by demanding "a court-martial" before the board of trustees and the formulation of specific charges. This mode of procedure was not adopted, but Dr. Kemp appeared before the board two or three times, presenting witnesses and papers to prove his success as a teacher and investigator, and calling attention to alleged defects in the organization of the university. Then finding the opposition to him still undefined and undiminished, he resigned his position and has since been waging war from the outside against President James and "the system." The board of trustees, regarding his resignation as voluntary, refuses to reopen the case and holds that he had no just grievance against the administration.

Dr. Kemp bases his charge of duplicity and unfair treatment chiefly on the fact that after his last appearance before the board his case was discussed by the president, who at that time stated his opinion of Dr. Kemp and why he did not regard him as worthy of promotion.

We do not see that this charge is well founded. We do not see why the technicalities of legal procedure should be followed in such cases. Certainly our courts are not so prompt and efficient in their action as to commend their methods for extension into academic circles. It is the business of boards to talk over freely the qualifications and defects of the professors, and they would be seriously hampered in their consideration of the subject if the individuals discussed had to be present or represented by attorney.

The reason why no definite and serious charges such as would necessitate his dismissal were brought against Dr. Kemp was probably because there were none to bring. The president seems to have objected to him on the ground that he was not a first-class teacher or administrator and that he was a hard man to get along with. These are as intangible as they are important, and it is difficult to see how they could be proved or disproved by any form of court-martial. President James practically appealed to the trustees to express their confidence in his judgment of men, and this is what they have done. Since to be a good judge of men is one of the most important qualifications of a college president, they could hardly have decided against him if they thought him worthy of office. It may be that President James underestimated Dr. Kemp's ability and overestimated his incompatibility, but the error, if it were such, does not involve any moral obliquity. The University of Illinois should have the best physiologist it can find, and it is not clearly demonstrated that Dr. Kemp is that man.

We believe that the board of trustees are right in holding that further discussion of the case is unnecessary and detrimental, although we do not regard their resolutions, reported in *The University of Illinois Press Bulletin* of December 16, as satisfactorily worded. We do not find in Dr. Kemp's letter of resignation the reasons they quote as his. The letter as published in *SCIENCE* gave altogether different reasons. And the statement made by the board that Dr. Kemp's resignation was not even suggested at the board meeting is quite too sweeping an assertion.

On the whole, we fail to find evidence to prove that academic freedom is in danger in the University of Illinois or that President James is more autocratic than other successful presidents, as, for example, our revered President Eliot. He certainly is less inclined to be arbitrary and dictatorial than his predecessor, President Draper. We can not here enter upon the wider question of whether a more democratic system of government, such as is advocated by Professor Cattell, is desirable. At present the tendency is to regard a stronger centralized and personal administration as best for universities and cities. The liability to abuse such power is checked by the watchfulness of supervising boards and by the fact that an aggrieved party may appeal to Cæsar, i. e., *SCIENCE*.—*The Independent*.

SCIENTIFIC BOOKS

Essays on Evolution, 1889-1907. By E. B. POULTON, Hope Professor of Zoology in the University of Oxford. Oxford, Clarendon Press. 1908.

Professor Poulton is well known as an ardent neo-Darwinian and as one who has made the subject of insect mimicry his own, the wonderful collection illustrating this interesting phenomenon in the Hope department of the Oxford Museum being a monument to his enthusiasm, energy and information in this field of investigation. In the volume of essays now under review these two topics are very much in evidence, the essays being for the most part addresses delivered by the author on various occasions, now brought up to date and reprinted. Inasmuch as the essays dealing with the Darwinian theory were originally written before the theory of mutations and Mendelism had become important factors in the question of the origin of species, Professor Poulton has added an introduction to his book dealing with these topics and protesting against the extreme position taken by those whom Professor Hubrecht, himself an upholder of the mutation theory, has lately characterized as "silly antagonists of Darwinism and evolution, who have thought fit to proclaim with a loudness that is in inverse ratio

to the square of their accuracy that Darwinism has been played out since the appearance of de Vries's 'Mutations-theorie.' It can not be said that Professor Poulton doth protest too much, but he certainly errs in the same direction as those against whom his protest is directed, in that he endeavors, unnecessarily for his purpose, to minimize the importance of both mutations and Mendelism, instead of recognizing them as factors in bringing about conditions upon which natural selection may act.

The first essay is a discussion of the age of the earth, considered from the standpoint of an evolutionist, and had for its exciting cause Lord Salisbury's presidential address to the British Association at the Oxford meeting in 1894. The question is an old one and has had many answers, none of which are very definite, nor does Professor Poulton's discussion of it lead to any more definite conclusion than that the earth must be old enough to have allowed time for the accomplishment of evolution. This will, no doubt, be quite acceptable to evolutionists. Similarly, the second essay, on "What is a Species?" while interesting as a discussion of the meaning that has been applied to the word species at different times, naturally leaves one with a sensation of indefiniteness, and the three succeeding essays, on "Theories of Evolution," "Theories of Heredity" and "The Bearing of the Study of Insects upon the Question 'Are Acquired Characters Hereditary?'" discussions of the respective merits of the old antagonists, Lamarckism and Weismannism, while more interesting reading than the majority of such discussions, yet, again, are quite as futile as these so far as any settlement of the questions at issue are concerned.

The sixth and seventh essays are largely historical. The sixth deals with the views concerning inheritance advanced by the anthropologist, Prichard, in his "Researches into the Physical History of Mankind" (2d edition, 1826). These constitute a remarkable anticipation of the conclusions later advanced by Weismann concerning the non-transmissibility of acquired characters, as a quotation

of one sentence from the work will suffice to show. Prichard says "changes produced by external causes in the appearance or constitution of the individual are temporary, and, in general, acquired characters are transient; they terminate with the individual, and have no influence on the progeny."

In the seventh essay Huxley's position on the question of natural selection is considered, and it is maintained that he "was at no time a convinced believer in the theory." This conclusion can not but seem strange when one recalls that Huxley received from Darwin the title of "general agent" by the vigor with which he wrote and spoke on behalf of the new theory. Professor Poulton certainly makes out a strong case, claiming that Huxley, while a strong evolutionist, was unable to appreciate the bearings of the theory of natural selection, his inclinations being towards the study of the "engineering side of nature," rather than towards the contemplation of structure in relation to environment. But in opposition to Professor Poulton's conclusion one may oppose Huxley's own statements. Writing to Darwin in 1859 he says:

As to the first four chapters [of the Origin], I agree thoroughly and fully with all the principles laid down in them. I think you have demonstrated a true cause for the production of species, and have thrown the *onus probandi*, that species did not arise in the way you suppose, on your adversaries.

True, he goes on to confess that he did not feel that he had fully realized the bearings of the theory of natural selection, and criticizes the adoption of the principle that *natura non facit saltum* and the slight importance assigned to continued physical conditions as a cause of variations. These criticisms do not, however, apply to the theory of natural selection; they concern only the question of the origin of variations. Further, writing in 1880, he said:

I hope you do not imagine because I had nothing to say about "natural selection" [in "The Coming of Age of the Origin of Species"], that I am at all weak of faith on that article. On the contrary, I live in hope that as paleontologists work more and more . . . we shall arrive at a

crushing accumulation of evidence in that direction also.

These statements can hardly be regarded as those of an unbeliever, but suggest the possibility that Professor Poulton is speaking in his essay as a neo-Darwinian, an upholder of the doctrine of the all-sufficiency of natural selection.

The latter part of the Huxley article and the remaining three essays are devoted to a consideration of the question of insect mimicry. They are the *pièces de résistance* of the whole volume, forming, as they do, the most thorough exposition of the significance of insect coloration we possess or are likely to possess until the fuller treatise promised by the author is published. In the abundance of illustrations cited and in the keen criticism to which the various cases are subjected the essays stand alone, and their usefulness is immensely increased by the addition of a list of the mimicking and mimicked forms referred to, and also by the most complete and thorough index to the entire volume that it has ever been the present reviewer's pleasure to use. If any points may be selected for special mention from a treatise whose general excellence is so high, they are the evidence advanced tending to place the Mullerian theory of common warning coloration on a firmer basis, and the extension of its applicability to a greater number of cases at the expense of the Batesian theory of mimicry.

What has been said above is intended as a review of the book from the standpoint of a biologist. To non-biological readers the perusal of every essay will be both pleasurable and profitable; pleasurable because Professor Poulton's style is admirable and both his description of facts and his statement of criticisms clear, and profitable because his information concerning the topics of which he treats is extensive. Accuracy is never sacrificed to an attempt to popularize the subject; such a defect is unnecessary in the writings of one who has so marked a faculty for the exposition of scientific topics in a manner intelligible to the general reading public.

J. P. McM.

THE GENERA OF AFRICAN PLANTS

THE agricultural, commercial and industrial activity of Europeans in Africa has been so great of recent years that the interior of that great continent has become to-day perhaps the most eagerly exploited field in descriptive botany, not even excepting the Philippines under American administration.

Though the British and French pretty evenly divide honors in the earlier study of African botany, and the former are likely long to maintain their lead in knowledge of the Cape flora, other nations have contributed very materially to our knowledge of the dark continent; and despite the fact that England was the first to press into the tropical interior, the present development of the latter has fallen largely to the Germans and Belgians.

To botanists possessed of collections of African plants, no recent publication is likely to be more directly and frequently helpful than Thonner's "*Blütenpflanzen Afrikas*." This stately volume brings together in synoptical form the scattered skeletal elements of the flora as a whole. Nomenclature, taxonomy and general ideas of segregation follow the Berlin practise. Well-contrasted keys are provided for the differentiation of families, and, under them, of genera: and the illustrations, from original drawings, simplify the application of text-characters. Indexes to popular and Latin names of plants add to the value of the book.

One of the most interesting features of the manual is a tabulated conspectus of the known African plants, which may be summarized as follows:

Distribution.	Families	Genera	Species
Total known	285	9,942	136,000
African	221	3,048	39,000
Indigenous	213	3,486	38,600
North African		981	4,850
Middle African		2,185	18,300
South African		1,393	13,300
Insular		1,266	5,950

¹Thonner, F., "*Die Blütenpflanzen Afrikas: Eine Anleitung zum Bestimmen der Gattungen der afrikanischen Siphonogamen*," Berlin, Friedländer, 1908, pp. xvi + 673, pl. 150, 1 map.

Though the families not represented in Africa are mostly of local distribution elsewhere and usually little differentiated into genera or even species, a comparatively few, like Magnoliaceæ, Styracaceæ and Polemoniaceæ, are elsewhere widely distributed and extensively differentiated. To one accustomed to the weeds of highly agricultural countries outside the tropics, with extensive interchange of the wares of commerce, the introduced plants of Africa appear peculiar, Araceæ, Zingiberaceæ and Myrtaceæ being prominent among them while our own customary weed groups like Gramineæ, Labiata, Caryophyllaceæ, Chenopodiaceæ, Amaranthaceæ and Umbelliferæ are either unrepresented or little prominent.

If a much larger number of thumb-nail details of genera had been substituted for full-plate illustrations of species, and if references had been given to monographs by aid of which the African species of a genus might be determined, the book would have been more useful: but even without these it is going to prove very helpful to those who study African plants in the field, herbarium or garden.

W. T.

Neurological and Mental Diagnosis. A Manual of Methods. By L. PIERCE CLARK, M.D., and A. ROSS DIFENDORF, M.D. New York, The Macmillan Company. 1908.

The title of this work is a misnomer. The book might be called a primer of nomenclature of nervous and mental symptoms, with description of the simpler methods of examination technique, but exclusive of all the methods of actual neurological and psychiatric diagnostic reasoning. This holds especially for the neurological part, which gives only a very elementary description of routine of examination which could hardly be called sufficient to lead to a diagnosis in a fairly large number of cases with vital issues involved.

The second part is an epitome of terms and definitions in psychiatry and ways of getting hold of the corresponding facts, with the addition of a standard case for each of the three standard types of dementia præcox, for de-

mentia paralytica or paresis, melancholia, "the" two forms of manic-depressive insanity, paranoia, alcoholic hallucinosis and amentia, arranged in the set formula assumed for the average examination. This is followed by twenty-eight pages of a "glossary of terms commonly used in psychiatry," adding materially to the scholastic tenor given the whole presentation. Very satisfactory photographs of the patients accompany most of the histories. The photographs and drawings of the neurological part give the positions in testing for reflexes, and the points of electric stimulation and the sensory segments.

There is no doubt about the desirability of outlines of examination, especially if they are sufficiently perspicuous in the arrangement of topics and the various steps to be followed to serve *during examinations*, and if they are small enough to be carried in the pocket, or still better, if they serve as a sort of portfolio, as a support in writing, as well as a protection against oversights. Neither of these purposes is served by the book, nor can it be called more than a partial summary of the ordinary methods and their technique, with the chief point, namely, the safeguards about interpretation, left practically untouched.

As a sample specimen of the neurological work a composite case record—under the best of circumstances likely to be a libel against nature—is furnished with the heading:

Oct. 1, 1907. William Johnson, 36, s., Eng., in U. S. 10 years.

Diagnosis: Tabes Dorsalis.

In the course of the not especially clearly arranged notes, without any evidence of change of heading or diagnosis or suggestion as to what was aimed at, we find the man married at 22, with 3 children; then—"one year ago (Oct., 1904)" a symptom-complex suggesting cerebral syphilis is credited to him, and in the direct examination the patient is a "blond German," but still 36 years old. The chief danger of records, the prevalence of form over sense, is unnecessarily and unintentionally exemplified.

In the review of the methods in a mental diagnosis the essential facts of the neurological diagnosis are done over. The general

plan of psychological examination may have the advantage of didactic simplicity, but it will lead rather to the picking out of a verbal diagnosis than to an understanding of the meaning and spirit of the disorder of the patient.

The mental cases given are clear but very elementary and there is very little help towards finding the way, where actual difficulties would arise.

In a future edition the grouping and the interpretation and utilization of the results should be given better attention, and by using different types of print the important and obligatory steps might be put into contrast with the matters to be used to settle less common difficulties.

A. M.

SCIENTIFIC JOURNALS AND ARTICLES

The Bulletin of the Charleston Museum for November comprises Notes on Taxidermy, Library News, Notes from the Museum and notices of The Natural History Society. The sound advice is given to those interested in taxidermy to practise on English sparrows and not endeavor to mount a bird until they can put up a good skin. The library possesses some interesting portraits of former officers and a bust of Bachman.

The Museum Journal of Great Britain for November contains accounts of the "Oxford Museum Jubilee" and the "Museum Conference in Rochdale" and "The Arrangement of an Egyptological Collection," by W. E. Hoyle. This comprises a suggested classification of exhibits and three alternative schemes for arrangement, chronological, topical and ideal, the latter being an effort to present a general view of Egyptian civilization. Arthur Fairbank presents the plans for "The New Building for the Museum of Fine Arts in Boston."

The Zoological Bulletin, Division of Zoology, Pennsylvania Department of Agriculture, though dated September 1, has only recently been received. It is devoted to a "First Report on the Economic Features of Turtles of Pennsylvania" and is a companion volume to the serpents of Pennsylvania previously is-

sued. The report comprises descriptions of all the turtles found in Pennsylvania, with accounts of their habits, value as food, and their beneficial or harmful character as indicated by the plants and animals on which they feed. The large amount of information as to habits and the food of turtles makes the paper particularly valuable. Half-tone plates, mostly provided from the American Museum of Natural History, are given of the various species and there are also in the text many most excellent pen drawings by W. R. Walton. Two original plates show good series of the variable and closely related species *Chrysemys marginata* and *C. picta*. Mr. Surface is to be congratulated on having placed so much information within reach of so many readers.

SPECIAL ARTICLES

THE TEXAS TERTIARIES—A CORRECTION

THE original section of the Texas Tertiary published in the *Journal of Geology* for 1894 made the Eocene end with the Frio substage of the Claiborne, which was followed immediately by the Oakville beds of supposedly Miocene age. Based on this classification and on the decision of Professor G. D. Harris that fossils found in sandstones just north of Corrigan were of Claiborne age, Mr. Kennedy referred these sandstones to the Fayette sand and the overlying or Fleming clays to the Frio. Larger collections from this locality made later by Mr. Veatch proved the Jackson age of the sandstones and this implied a similar wrong assignment on our part of the Frio clays. From Mr. Veatch's statement in his report "Underground Water Resources of Northern Louisiana and Southern Arkansas," he evidently considered the reference of the Corrigan beds as made by Kennedy incorrect, and our recent stratigraphic work on them has proved this to be true.

On the Rio Grande, Nueces and San Antonio rivers, and probably on the Colorado, the original section holds, and the Frio beds which carry Eocene fossils in places are immediately overlain by the Oakville. In the eastern part of the state, however, beds of Jackson age appear in places between the Frio and Oakville.

On the Houston East and West Texas Railway, the sands which really represent the Fayette beds occur around Lufkin, but the exposures on the railroad, where the section was originally made, are so small that they were considered as simply a part of the Yegua beds, which were thereby given a much greater areal distribution than elsewhere and made to include the overlying Frio clay as well.

The contact between the Yegua and Fayette should have been given as just north of Lufkin and the Frio clays should have been shown as occupying the area between Burke and the top of the bluff on the south bank of the Neches River. At this latter point, we have the contact of the sandy limestone containing Jackson fossils, and this is overlain by the Fleming-Burkeville beds, while the Oakville sands appear just south of Corrigan. Similar conditions exist east and northeast of Corrigan to the Sabine River, and it is altogether probable that some of the deposits lying to the west and classed by Kennedy as Navasota beds may belong to this same horizon.

The same section is also shown on the Conchas River in Tamaulipas, Mex., where the Fayette sand, with its characteristic fossil *Ostrea alabamiensis* var. *contracta* is overlain by the Frio clays and these in turn by sandstones with a distinct Oligocene fauna.

It would therefore appear that while the Oligocene was probably laid down entirely across this area, it is now covered in many places by the overlapping Oakville.

E. T. DUMBLE

THE SIXTIETH MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE, BALTIMORE, MD.,
DECEMBER 28-JANUARY 1, 1909-9

ONE of the most successful meetings in the history of the American Association, and in some regards the most successful, was brought to a close Friday evening, January 1, 1909, at Baltimore. Ample provisions for a large meeting were made by the local committee, and the expectations were fully realized. The total registration of the members of the association was 1,088 and the affiliated societies reporting adds 117. The next largest registration to this was at Washington, in 1903, when 903 were recorded. But, as always,

many in attendance were not registered, and a conservative estimate would bring the attendance of scientific men up to about 2,000. One striking feature in the attendance was the large number of men from the various government services in Washington, who came over and lent their presence in the meetings of every section.

Great credit is due to the energy and efficiency of the local committee, of which Professor Wm. H. Welch was chairman and Professor Wm. J. A. Bliss secretary. The meeting places, mostly in the buildings of the Johns Hopkins University and Medical School, were ample and convenient, and the hotel accommodations excellent. There was not a hitch in the carrying out of the program; every want was provided for in advance.

The opening session was held in the audience room of McCoy Hall, Johns Hopkins University, at 10 A.M. Monday, December 28, 1908, with the retiring president, Professor E. L. Nichols, of Cornell University, in the chair, who introduced the incoming president, Professor T. C. Chamberlin, of the University of Chicago, who presided. Addresses of welcome were made on behalf of the educational institutions of the city by President Ira Remsen, on behalf of the local committee by Dr. Wm. H. Welch and on behalf of the city of Baltimore by the mayor, Hon. J. Barry Mahool. It was recalled that when the association met in Baltimore fifty years ago, the membership was only 1,000 and the attendance at the meetings only 200, while now the membership has grown to 7,000 and the association has been divided into eleven sections, each devoted to a phase of scientific work, and even sections subdivided, in the case of Section C, chemistry, there being eight subsections, each with large attendance, and papers enough to occupy two or three days in the reading.

The presidential address by Professor E. L. Nichols, of Cornell University, was given in the hall of the Peabody Institute before a large audience of members and citizens of the town. The address was a masterly presentation of the thought that all the material advance of society is based on the discovery of laws and the establishment of principles by research in pure science; that the most of this research and of these contributions up to date have been made in lands across the sea; that our universities are not properly providing for research, and that great improvement along these lines is possible, the recent noble bequest of Senator Vilas to the University of Wisconsin for the endowment of research professorships pointing the way.

After the presidential address a reception to the members of the association and affiliated societies was tendered by President Ira Remsen at McCoy Hall. The reception was largely attended and was a very pleasant affair.

Sectional meetings began on Monday afternoon, and were continued till Friday evening, when all papers were read or otherwise disposed of. Certain of these sectional meetings were favored with record attendance, and with programs of exceptional interest and value. Section B reports the most successful meeting of its history. The joint meeting with the American Physical Society gave a record attendance. It was probably the largest gathering of physicists that has ever occurred in America. Eight sessions were held, and 54 papers presented. The dinner held at the Country Club on Tuesday evening had an attendance of 91 and was voted the pleasantest event in the history of the section.

Section E, in affiliation with the Geological Society of America, held a memorable symposium on "Correlation in Historical Geology." Sixteen papers were presented in this symposium, running through six sessions. A feature was a remarkable series of maps by Mr. Bailey Willis, showing the paleogeography of the continent of North America in many stages of its formation up to the present, showing what was certainly land, and certainly sea, areas sometimes land and sometimes sea, and the areas of uncertainty. Quite significant was the presentation of the logic of correlation by Professor T. C. Chamberlin, the first term in every series of phenomena to be interpreted being shown to be found in diastrophic changes.

The most important event in the week for Section F was the vice-presidential address by Professor E. B. Wilson, on "The Determination and Inheritance of Sex."

Section L reported a very successful series of meetings, thus proving the wisdom of its establishment last year. This section has adopted the plan of devoting each session to the discussion of a single topic. On Wednesday afternoon American College Education was the theme, discussed by Professors Josiah Royce, James H. Tufts and others. In his address as retiring vice-president Commissioner Elmer E. Brown pointed out effectively the chaos that exists in American educational standards, and defined clearly some of the problems that must be solved to bring order out of this chaos. A session was devoted to the discussion of the needs and possibilities of the U. S. Bureau of Education.

The affiliated societies meeting with the asso-

ciation this year were the American Society of Naturalists, the American Society of Biological Chemists, the American Anthropological Association, the American Folk Lore Society, the American Philosophical Association, the American Physical Society, the American Psychological Association, the American Physiological Society, the American Society of Vertebrate Paleontologists, the American Chemical Society, the American Society of Zoologists, the American Nature-study Society, the American Mathematical Society, the American Federation of Teachers of the Mathematical and the Natural Sciences, the American Institute of Electrical Engineers, the American Alpine Club, the Association of American Geographers, the Association of American Entomologists, the Botanical Society of America, the Entomological Society of America, the Geological Society of America, the Society of American Bacteriologists, the Association of American Anatomists, the Southern Society for Philosophy and Psychology, the Sullivant Moss Society and the Wild Flower Preservation Society.

Some actions of the council of the association are of general interest: A resolution was adopted authorizing the permanent secretary to send a letter of greeting to Dr. Martin H. Boyé, of Cooperstown, Pa., the sole surviving founder of the association. It was resolved that the publishers of *SCIENCE* and *The Popular Science Monthly* be authorized to send *The Popular Science Monthly* in place of *Science* to any members of the association who may specially request it.

An amendment to the constitution was introduced as follows: Amend Article 23, by the omission of the words "and secretary" after the word "vice-president," in the third line, and to insert after the words "preceding meeting," in the fourth line, the following words: "and the preceding secretary, and the presidents and secretaries of those affiliated societies which shall be designated by the council."

One of the pleasantest features of the week was the reception, largely attended, on Tuesday afternoon from 4 to 6:30, by the Maryland Historical Society at its rooms on Saratoga and St. Paul streets.

Quite significant and worthy of attention was the symposium on "Tariff Revision," by Section I on Tuesday afternoon; with papers by Messrs. Farquhar, Hamilton, Orton and Holt, and discussion by Dr. J. Franklin Crowell, of the *Wall Street Journal*, and Mr. Seymour C. Lewis. The recommendation of the last named gentleman, that the laboratory method be introduced into the tariff

management, by establishing a bureau in the Department of Commerce and Labor, composed of experts, who will make scientific studies and recommendations to Congress, so removing the question from partisan politics.

Another valuable meeting was the symposium on "Public Health" in McCoy Hall on Thursday afternoon, with addresses by Dr. Harvey W. Wiley, of the Bureau of Chemistry, Washington, on "The Nation's Pure Food Problem"; by Dr. L. O. Howard, on "The Economic Loss due to Insects that Carry Disease"; by Dr. Horace Fletcher, on "Vital Economics"; by Professor Irving Fisher, of Yale, on "Progress of the Movement for Health Reform"; and by Dr. Walter Wyman, of Washington, on "Public Health Administration." The very great preventable waste of human life, which is going on around us, was forcibly presented, and recommendations made for our government to take an intelligent and earnest interest in conservation of health as our greatest resource.

The crowning feature of the week was the Darwin Centenary Memorial. The entire day, Friday, was devoted to the celebration. The great audience room of McCoy Hall was filled to the doors during the presentation of the papers. The president of the association, Dr. T. C. Chamberlin, presided and opened the session with an address. Then followed Dr. Edward B. Poulton, of Oxford University, England, who spoke very entertainingly of "Fifty Years of Darwinism"; Professor John M. Coulter, of the University of Chicago, spoke on "The Theory of Natural Selection from the Standpoint of Botany"; and Professor E. B. Wilson, of Columbia University, discussed "The Cell in Relation to Heredity and Evolution." In the afternoon session Dr. Daniel T. MacDougal, of the Carnegie Institution, told of the "Direct Effect of Environment"; Dr. S. W. E. Castle, of Harvard University, explained "The Behavior of Unit Characters in Heredity"; Dr. Charles B. Davenport gave an account of "Mutation"; Dr. Carl H. Eigenmann, of Indiana University, discussed "Adaptation"; Professor Henry F. Osborn, of Columbia University, gave "Recent Paleontological Evidence of Evolution." This series of addresses will be issued as a memorial volume a little later in the year.

The close of the week's functions was the Darwin memorial dinner at Lehman's Hall. About 300 sat at table, and after the repast the president of the association, Dr. Chamberlin, presented Professor H. F. Osborn as the toast-master. Professor Osborn gave an interesting reminiscence of his youth, when working in Huxley's labora-

tory. Darwin visited the place, as the guest of Huxley, and the young Osborn, being the only American present, was introduced to Darwin. He spoke also of the spirit of Darwin and of Huxley which came to Johns Hopkins with Martin and with Brooks, both now gone. Professor Wm. H. Welch was then introduced and spoke of "The Debt of Medicine to Darwin"; Dr. Albrecht Penck, of the University of Berlin, spoke on "The Geographical Factor in Evolution," and Professor Edward B. Poulton, of Oxford, gave a lively and entertaining talk on "The Personality of Darwin." Then Professor Chamberlin closed the meeting with words of thanks and praise for those in Baltimore who so splendidly entertained the association.

At the final general meeting on Friday morning a resolution, introduced by Mr. Edward W. Morley, was passed, as follows:

Resolved, That the American Association for the Advancement of Science sincerely thanks the Johns Hopkins University and the other institutions of the city and also the citizens of Baltimore, for their generous hospitality during our meeting.

At the meeting of the general committee it was voted to hold the next meeting during convocation week, 1909-10, at Boston, and recommendations to following councils favoring successive annual meetings at Minneapolis, Washington, Cleveland and Toronto. It was voted that a summer session in 1910 at Honolulu would be desirable if suitable arrangements can be made.

Officers were elected as follows: President, Dr. David Starr Jordan, of Leland Stanford University; General Secretary, Professor Dayton C. Miller, Case Scientific School, Cleveland; Secretary of Council, Dr. F. G. Benedict, of the Carnegie Institution; Secretary of Section H, Professor George Grant McCurdy, of Yale University; Secretary of Section K, Dr. G. T. Kemp. Vice-presidents of the various sections were elected as follows: Section A, Professor E. W. Brown, of Yale University; Section B, Dr. L. A. Bauer, of the Carnegie Institution; Section C, Professor Wm. McPherson, of Ohio State University; Section D, Mr. J. F. Hayford, of the U. S. Coast and Geodetic Survey, Washington; Section E, Dr. R. W. Brook, director of the Canadian Geological Survey; Section F, Professor W. E. Ritter, University of California; Section G, Professor D. P. Penhallow, McGill University, Canada; Section H, Professor Wm. H. Holmes, chief of the Bureau of Ethnology, Washington; Section I, Dr. Carroll D. Wright, of Clark College; Section K, Professor C. S. Minot, Harvard University; Section L, Dr.

James E. Russell, Teachers College, Columbia University.

J. PAUL GOODE,
General Secretary

UNIVERSITY OF CHICAGO

THE AMERICAN MATHEMATICAL SOCIETY

The fifteenth annual meeting of the society was held at Baltimore, Md., on Wednesday and Thursday, December 30-31, in affiliation with the American Association for the Advancement of Science. The total attendance at the four sessions was about seventy-five, including fifty-seven members of the society. Wednesday evening was set apart for a dinner, at which forty-five of the members were present.

The sessions opened at 10:30 A.M. and 2 P.M. on each day. President H. S. White occupied the chair, being relieved by Professor Morley and Vice-presidents Miller and Kasner. At the opening of the afternoon session on Wednesday President White delivered his retiring address on "Bézout's theory of resultants and its influence on geometry." The council announced the election of the following persons to membership in the society: Professor G. N. Armstrong, Ohio Wesleyan University; Professor P. F. Gaehr, Robert College, Constantinople; Dr. Frank Irwin, Princeton University; Miss Mary E. Wells, Mount Holyoke College. Six applications for membership were received. The total membership of the society is now 602, including 55 life members.

At the annual election, which closed on Thursday morning, the following officers and members of the council were chosen:

President—Professor Maxime Bôcher.

Vice-presidents—Professors Edward Kasner and E. B. Van Vleck.

Secretary—Professor F. N. Cole.

Treasurer—Professor J. H. Tanner.

Librarian—Professor D. E. Smith.

Committee of Publication—Professors F. N. Cole, D. E. Smith, Virgil Snyder.

Members of the Council to serve until December, 1911—Professors H. B. Fine, O. D. Kellogg, F. R. Moulton, E. J. Wilczynski.

The treasurer's report shows a balance of \$2,225.80, including the life membership fund of \$2,225.20. Disbursements, including the cost of publishing the *Bulletin* and *Transactions*, were \$2,573.97. Sales of publications amounted to \$2,225.36. The library now contains over 3,000 volumes. The Annual Register of the society, containing the list of members, constitution and

by-laws, annual reports and catalogue of the library, is now in press and will be issued this month.

The following papers were read at the annual meeting:

R. D. Carmichael: "On r -fold symmetry of plane algebraic curves."

R. D. Carmichael: "A general principle of inversion, with applications."

W. R. Longley: "Some sufficient conditions in the theory of implicit functions."

C. L. E. Moore: "Properties of systems of lines in space of four dimensions and their interpretation in circle geometry."

F. R. Sharpe: "The topography of the integral curves of a differential equation."

Joseph Lipke: "Note on isotropic ruled surfaces."

John Eiesland: "On a species of cubic surfaces of the sixth class."

E. O. Lovett: "Integrable problems of three bodies."

J. I. Hutchinson: "On linear transformations which leave an Hermitian form invariant."

H. S. White (presidential address): "Bézout's theory of resultants and its influence on geometry."

Frank Morley: "Plane sections of the Weddle surface."

G. A. Miller: "Finite groups which may be defined by two operators satisfying two conditions."

F. L. Griffin: "Tests comparing the apsidal angles and periodic times for different laws of central force."

E. G. Bill: "Existence 'im Kleinen' of a space curve which minimizes a definite integral."

E. G. Bill: "An a priori existence theorem in three dimensions for the calculus of variations."

J. R. Conner: "Curves and surfaces which admit configurations of the Cayley-Veronese type."

D. D. Leib: "The complete system of invariants for two triangles."

W. A. Granville: "Dual formulas in spherical trigonometry."

C. J. Keyser: "Concerning euclidean geometries without points and lines."

M. E. Sinclair: "The problem of the surface of revolution with two end points variable on circles."

G. A. Bliss: "On the construction of the coordinate system of analytic projective geometry."

O. N. Haskins: "Numerical computation of reaction velocity constants."

Edward Kasner: "The group generated by turns and slides."

Edward Kasner: "Catenaries in an arbitrary field of force."

W. B. Carver: "Degenerate pencils of quadrics connected with Γ_{n+1}^2 configurations."

C. F. Craig: "On a class of hyperfuchsian functions."

Virgil Snyder: "Surfaces and congruences derived from the cubic variety having a double line in four-dimensional space."

W. B. Ford: "Irreducible homogeneous linear groups in an arbitrary infinite field."

Arthur Ranum: "On certain solids in riemannian space."

Arthur Ranum: "On the rank of a matrix."

H. B. Phillips: "Polygons on a quadric surface."

J. G. Hardy: "Note on a theorem of Pironi concerning four-dimensional curves."

E. B. Coble: "Combinants of binary forms."

The twenty-fourth regular meeting of the Chicago Section was held at the University of Chicago on Friday and Saturday, January 1-2. The next meeting of the society falls on Saturday, February 27, at Columbia University. The San Francisco Section will meet on the same day at Stanford University. The sixteenth summer meeting and sixth colloquium will be held at Princeton University during the entire week September 13-18. The first two days will be devoted to the regular sessions for the presentation of papers. At the colloquium, which will open on Wednesday morning, the following special courses of lectures will be given: Professor G. A. Bliss, "Existence theorems in analysis"; Professor J. H. Jeans, "Statistical mechanics"; Professor Edward Kasner, "Geometric aspects of dynamics."

F. N. COLE,
Secretary

SOCIETIES AND ACADEMIES

THE INDIANA ACADEMY OF SCIENCE

THE annual meeting of the Indiana Academy of Science pursuant to the new plan of holding meetings at the various institutions of learning in the state, was held at Purdue University on November 26-28. A large representation of the educators of the state was present and many papers were read that were of interest and importance. Thirty-five names were added to the roll of the membership, and a number of men who once were residents of the state and active members of the academy were elected to non-resident membership. The retiring president, Professor Glenn Culbertson, of Hanover College, delivered

an address on the subject "Deforestation and its Effects among the Hills of Southern Indiana." Significant among the papers read was the number bearing on practical scientific problems. Following is the program in full.

General

"Work of the Pathological Laboratory of the Central Indiana Hospital for the Insane," Dr. Geo. F. Edenharter.

"New Species of Birds in Indiana," James Butler.

"The Recent International Congress on Tuberculosis," Severance Burrage.

"Biography and the Influence of Environment," Robert Hessler.

"Folkner Island, Waber Lake, Kosciusko County, Indiana," J. P. Dolan.

"A Strange Nurse," A. J. Bigney.

"Drawing of the Indians at 'Shaker' (made by an Indian in the Indian School), presented by Albert B. Reagan.

"Invasion of a School Building by Bedbugs, *Acanthia hirsutinis*, parasites on Chimney Swifts," H. E. Enders.

"Photographs of Morehouse's Comet, 1933" (lantern), W. A. Cogshall.

"Selective Fertilization among Fishes," W. J. Moenkhaus.

"Nature Study," J. G. Coulter.

Botany

"Field Observations on Rusts for the General Botanist," J. C. Arthur.

"The Rust of Timothy," F. D. Kern.

"Notes on the Heterocercous Rusts of Indiana," Aaron G. Johnson.

"Some Anomalies in the Endosperm of *Pisum*," D. M. Mottier.

"Notes on the Seedless Persimmon," Wm. E. Woodburn.

"A Preliminary List of the Fungi of Indiana," J. M. Van Hook.

"Testing Seed Corn by Specific Gravity," H. A. Dunn.

"Notes on the Flora of Cass County, Indiana," Robert Hessler.

"Bean Anthracnose," M. F. Barrus.

"Endophytic Algae," Jacob Schramm.

"Report of Work in Corn Pollination," M. E. Fisher.

"Effect of the Recent Drought upon Forest Trees," Stanley Coulter.

"Difference between *Pinus taeda* and *Pinus strobus*," Katherine G. Bitting.

"A Forest Problem," W. H. Freeman.

"Botany in the High School," E. C. Snarr.
 "The Killing of Mustard and other Noxious Weeds in the Grain Fields of Dakota," E. W. Gilva.
 "The Plankton of an Underground Stream," Will Scott.
 "Anthracnose on Cereals and Grasses," A. D. Selby and T. F. Manns.
Chemistry, Physics and Mathematics
 "The Meyer Molecular Weight Calculation," Percy N. Evans.
 "The Vapor Pressure Method of Determining Molecular Weights," J. B. Garner.
 "Reaction of Sulphuric Acid Interpreted upon the Basis of the Electrolytic Dissociation Theory," W. A. Ruth.
 "Action of Alpha Bromoacetyl esters on Sodium Acetylacetone," G. A. Reddick.
 "Action of Alpha Bromoacetyl esters on Sodium Benzoylacetone," J. B. Garner and G. J. Fink.
 "Relation of Fat to Moisture Content of Butter," O. F. Hunziker.
 "Note on a Class of Definitions," F. R. Higgins.
 "A Graphical Representation of the Epsilon-Delta Definition of the Limit of a Function and Continuity," F. R. Higgins.
 "The Beckmann Rearrangement," J. B. Garner.
 "A Contribution to the Chemistry of Mucoid," C. E. May.
 "Determination of Lead by Titration of Lead Chromate," C. E. Brooks.
 "An Evolution Method for the Determination of Sulphur in Sulphates and Sulphides," F. C. Mathers.
 "The Deterioration of Platinum through Ignition of Phosphates," R. E. Lyons.
 "The Use of the Polaroscope in Testing High Tension Insulators," C. F. Harding.
Geology
 "Probable Origin of Depressions in the Mesa South of the Tijeras Canyon, New Mexico," Albert B. Reagan.
 "Headwaters of the Tippecanoe River," J. T. Sevell.
 "Origin of Cyclones and Anticyclones of Temperate Latitudes," W. A. McBeth.
 "Some Drainage Modifications in Southern Indiana," W. M. Tucker.
 "Soil Survey of Davies County," L. C. Snyder.
 "Caves and Cave Formation of the Mitchell Limestone of Indiana," F. C. Greene.
Zoology
 "The Nasal Muscles of the Reptiles," H. L. Bruner.

"Swell Mechanisms of Vertebrates," H. L. Bruner.
 "Life Zones of Indiana as Illustrated by the Distribution of Orthoptera and Coleoptera within the State," W. S. Blatchley.
 "Animals of the Olympic Peninsula, Washington," Albert B. Reagan.
 "The Effect of Successive Removal on the Rate of Regeneration," Charles Zeleny.
 "Proportional Regeneration," M. M. Ellis.
 "Curves Representing the Rate of Regeneration," M. L. Durbin.
 "Evidences for the Circulation of a Mixed Blood in the Adult Reptile and Amphibian as well as in the Fetal Mammal and Bird," A. G. Pohlman.

The following were elected officers for the ensuing year:

President—A. L. Foley, State University.

Vice-president—P. N. Evans, Purdue.

Secretary—J. H. Ransom, Purdue.

Assistant Secretary—A. J. Bigney, Moore's Hill College.

Press Secretary—G. A. Abbott, Indianapolis Manual Training School.

Treasurer—W. A. McBeth, State Normal.

Editor—H. L. Bruner, Butler College.

J. H. RANSOM,

Secretary

THE PHILOSOPHICAL SOCIETY OF WASHINGTON

THE 656th meeting was held on December 5, 1908, Vice-president Wead in the chair. The evening was devoted to hearing the president's annual address, delivered by Dr. L. A. Bauer, who spoke of "The Instruments and Methods of Research."

The full text of this address will soon be published in volume XV. of the *Bulletins of the Philosophical Society of Washington*.

THE 38th annual meeting was held December 19, 1908, President Bauer in the chair.

The following officers were duly elected for the ensuing year:

President—Simon Newcomb.

Treasurer—Bernard R. Green.

Secretaries—G. K. Burgess and R. L. Faris.

General Committee—W. A. DeCaindry, R. A. Harris, E. Buckingham, E. G. Fischer, L. A. Fischer, L. J. Briggs, P. G. Nutting, W. S. Eichelberger, F. A. Wolf.

R. L. FARIS,

Secretary

THE BIOLOGICAL SOCIETY OF WASHINGTON

THE 449th meeting was held November 28, 1908, with President Stejneger in the chair. Mr. H. W. Clark noted the occurrence of maple seeds gathered into clumps and partly buried in the ground under the trees, without apparent reason. Dr. L. O. Howard cited a new problem in the distribution of the gypsy moth. Distribution has been supposed to be only by caterpillars dropped upon and carried by moving objects, as carriages and the like. Isolated colonies of the moth have now been found in the woods far from roads or paths. The moths can not fly and it is yet unknown how the dissemination was accomplished. Information or suggestions were requested, the point being of much practical importance. The part which birds or heavy winds may play is problematical.

The regular program consisted of an address by Dr. F. Orelighton Wellman on the "General Biological Conditions in Angola, Portuguese West Africa." The speaker occupied an hour with an interesting account of general conditions, citing freely from his notes, which were especially rich on the botanical side, on species of both flora and fauna in many groups.

THE 450th meeting was held December 12, 1908, in George Washington University Hall, with President Stejneger in the chair. The program consisted of an illustrated lecture by Mr. Ernest T. Seton, entitled "Two Thousand Miles by Canoe to the Arctic Region."

The 451st meeting, being the 29th annual meeting for the election of officers, was held December 26, 1908, with President Stejneger in the chair. The following were elected for the ensuing year:

President—T. S. Palmer.

Vice-presidents—E. L. Greene, E. W. Nelson, W. P. Hay, J. N. Rose.

Recording Secretary—M. C. Marsh.

Corresponding Secretary—W. H. Osgood.

Treasurer—J. W. Gidley.

Councilors—A. D. Hopkins, A. K. Fisher, A. B. Baker, David White, Vernon Bailey.

M. C. MARSH,
Recording Secretary

SECTION OF GEOLOGY AND MINERALOGY OF THE
NEW YORK ACADEMY OF SCIENCES

At the regular monthly meeting of the section on November 2, the evening was given to the presentation and discussion of a paper entitled "A Contribution to the History of Mt. Pelé, Martinique," by Dr. Edmund Otis Hovey.

The author described, with the aid of many

lantern slides, the conditions on and near Mt. Pelé during his visits in May-July, 1902, February-April, 1903, and April-May, 1908, and illustrated particularly the devastation wrought by the early eruptions, the disposition and distribution of material thrown out by the volcano, the building up of the spine of 1902-3 and its subsequent destruction, the advance of erosion since the cessation of eruptions and the restoration of vegetation in St. Pierre and upon the flanks of the mountain. The paper also described the area of fumaroles in the valley of the Rivière Claire and gave the arguments for the probability of these being true fumaroles. Temperature observations were made also in the great fissures of the new cone, where, by means of an electric pyrometer, temperatures as high as 515° C. (959° F.) were obtained.

The paper will be published in full in the *Bulletin of the American Geographical Society*.

CHARLES P. BERRY,
Secretary of Section

THE AMERICAN CHEMICAL SOCIETY
NEW YORK SECTION

THE third regular meeting of the session of 1908-9 was held at the Chemists' Club on December 11.

Messrs. H. S. Miner and M. C. Whitaker presented a paper on "The Rare Earths—their Production and Application." Mr. Miner spoke of the sources of the so-called rare earths, described the forms in which they occurred and the methods of mining and purifying them. He then gave a résumé of the development of incandescent gas lighting, describing the researches of the early workers on the subject and indicating many problems yet to be solved. Mr. Miner illustrated his subject by a splendid collection of raw and purified materials used in making Welsbach mantles. Mr. Whitaker described the manufacturing processes and different forms of mantles used in this country and abroad. He showed numerous lantern slides to illustrate the structure of the mantles and the machinery used in making them.

The other titles for the evening were as follows: "A Volumetric Method for the Determination of Barium," A. E. Hill and W. A. E. Zink; "The Ultra-microscope and some of its Revelations," Jerome Alexander; "The Potential of Iron Calculated from Equilibria Measurements," A. E. Lamb.

C. M. JONES,
Secretary

EARTHQUAKE FORECASTS¹

INTRODUCTION

THERE was a time when the weather belonged to the gods. Storms and drought were inflicted on man in punishment or for vengeance, man strove to avert them by sacrifice or prayer, and the priest was his intercessor. Now the weather belongs to nature, and the priestly robe has fallen on the Weather Bureau. Man's new agent, however, is not an intercessor; he does nothing to placate; he makes no attempt to control the course of nature; but inspired by science he foretells the coming changes so that his lay client may take warning and be prepared. The crops are harvested before the rain, the herds escape from the lowland before the flood, the ships reach harbor before the gale; and man chants a hymn of praise to science.

There was a time when the earthquake was equally enveloped in mystery, and was forecast in the enigmatic phrases of the astrologer and oracle; and now that it too has passed from the shadow of the occult to the light of knowledge, the people of the civilized earth—the lay clients of the seismologist—would be glad to know whether the time has yet come for a scientific forecast of the impending tremor. The outlook for earthquake forecasting is my theme to-day.

As you are aware, I am not a seismologist. My point of view is that of the geologist and general geographer. I speak as

¹ Presidential address to the American Association of Geographers, read at Baltimore, Md., January 1, 1909.

a layman, and present impressions acquired chiefly during somewhat amateurish work on the physical history of the San Francisco earthquake. That event was so far unforeseen that no seismologists were at hand, and the duty of investigation fell, in the emergency, on a volunteer corps of geologists and astronomers. For me it proved a fascinating subject, and interest did not cease with the completion of the special task.

But while this much is offered by way of explanation, and to prevent misunderstanding, you are not to infer that an apology is made because I trespass on fields to which I have no title, for I am an advocate of the principle of scientific trespass. The specialist who forever stays at home and digs and delves within his private enclosure has all the advantages of intensive cultivation—except one; and the thing he misses is cross-fertilization. Trespass is one of the ways of securing cross-fertilization for his own crops, and of carrying cross-fertilization to the paddock he invades. Hypotheses, the trial theories which compete for development into final theories, spring by the principle of analogy from earlier and successful theories, and the broader the investigator's knowledge of explanatory science the greater his opportunity to discover hypotheses that may be applied to his own problems. Progress is ever through the interaction of the sciences one on another; and scientific trespass is one of the profitable modes of interaction. The trespasser brings with him a mental attitude and a mental equipment which are new to the subject, and whether or no the idea he contributes eventually "makes good," its contribution creates a new category for observation and opens a new avenue of inquiry. And he carries back with him the pollen of new ideas.

Next to verity, the factors which give

value to an earthquake prediction are definiteness as to time and place. If the geologist Whitney, in warning San Franciscans forty years ago that their city would suffer by earthquake, had been able to specify the year 1906, and to convince them that he had warrant for his prophecy, the shock, when it came, would have been a phenomenon only and not a catastrophe. If any of those mysterious oracles who were said to have predicted earth convulsions in 1906 had named San Francisco, and told their reasons, the course of history might have been different.

PLACE

Let us consider first the possibility of scientific forecast as to place, and in so doing let us assume the point of view of the resident. The factor in which he is personally interested is the factor of danger—danger to life, danger to property, danger to the present generation. Except as a matter of curiosity, he is not concerned with faint tremors and minor shocks, nor with violent shocks likely to come after centuries of immunity. It will be convenient, at least for this day and hour, to embody our point of view in a concise term, and the adjective *mallo-seismic* will be used to designate localities likely to be visited several times in a century by earthquakes of destructive violence.

Experience.—The most important of all bases for the indication of earthquake localities is experience. Where tremors have been frequent in the past, there they are to be expected in the future. This premise hardly requires discussion, for it is founded on our confidence in the continuity of the great processes concerned in the evolution of the earth. We recognize indeed that continuity may fail in any particular case, but we always assume it as far more probable than discontinuity.

Other bases for forecast are connected with our conceptions as to the origin of earthquakes. The theory of earthquakes now generally accepted ascribes them to the sudden breaking or slipping of rocks previously in a condition of shearing strain. Exception should probably be made of some of the shocks accompanying volcanic eruptions, but volcanic shocks constitute a class by themselves to which it is not important to extend the present discussion. In non-volcanic, or ordinary, examples it is believed that the strains arise in connection with those tectonic or diastrophic changes which are exhibited superficially in the deformation of the surface, and that their accumulation is gradual. Fracture occurs when and where the internal stress exceeds the strength of the rock, and a fault results. Slipping takes place when the stress along the plane of a preexistent fault exceeds the force of adhesion. In either case it is the instantaneous character of the separation which occasions the jar.

The earthquake being thus a concomitant of tectonic change, its regions of frequency should be found in areas of diastrophic activity, and its occurrence should be rare and sporadic in areas of diastrophic sluggishness. This corollary is so well recognized that seismic activity is commonly regarded as the specific criterion of relatively rapid crustal change. Other criteria of such change are physiographic and geologic, and these may be applied in regions whose earthquake history is unknown. They may also be used, in the absence of seismic records, to give approximate indication of malloseismic localities.

Bold and High Ranges.—It was pointed out by Powell that, because erosion is greatly stimulated by altitude and high declivity, lofty mountains must be regarded as young; and under the principle of continuity young mountains created by

uplift are presumably still growing. They are, therefore, phenomena of diastrophic activity and presumably belong to malloseismic districts. The conspicuous example is Mt. St. Elias, which rises boldly 20,000 feet from its base, which was shown by Russell to have continued its growth during the life of the existing marine fauna, and which recently has been signalized by earthquakes of the first class.

Fault Scarps.—Along the bases of block mountains the lines of their limiting faults are sometimes marked by fresh scarps demonstrating recent increase of uplift. In the Great Basin these scarps traverse the alluvium of the piedmont slopes, a surface of such simple type that their presence or absence can be observed with confidence. Their absence suggests diastrophic inactivity or sluggishness, for their effacement is a time-consuming process. Their presence suggests diastrophic activity, and the suggestion is strengthened when their relation to phenomena of weathering and erosion is such as to show that they were produced by a series of recent uplifts instead of one only.

Rifts.—A third physiographic criterion is illustrated in California and was brought to general attention by the San Francisco earthquake. The slip causing that shock occurred on the plane of a fault which outcrops at the surface and has been traced for hundreds of miles. The attitude of the plane is vertical, but the displacement along it was horizontal; and there is reason to think that earlier movements on the same plane were horizontal also, for the fault does not separate a ridge of uplift from a valley of depression but traverses both valleys and mountains. At all points it is included within a belt of peculiar topographic habit, which the investigating geologists have designated as "the rift." Within this belt, which ranges in width from a fraction of a mile

to several miles, are numerous ridges and troughs, long or short, level or inclined, and approximately parallel to the trend of the belt. Each of these represents a dislocated tectonic block, and the dislocation is of so recent date that the disturbed drainage has made little progress toward the restoration of normal conditions. Lakelets are numerous, and streams wander irregularly. Without delaying to attempt a fuller and more adequate description, which may be found in the report of the California Commission,² I content myself with an assurance to physiographers that the topographic expression of the rift belt is distinctive, so that it can readily be recognized in other localities by those who have made its personal acquaintance in the field. Other belts of the same character have already been found in California³ and their discovery elsewhere may confidently be expected.

Rift topography appears to be the surface expression of a species of repetitive horizontal faulting, just as the fault scarp is the surface expression of vertical fault-

² California earthquake of April 18, 1906; report of the State Earthquake Investigation Commission; published by the Carnegie Institution, Washington, 1908, pp. 25-52.

³ The only rift belt beside the San Andreas which has yet been traced for any distance is one which follows in a general way the western base of the Berkeley hills. In the vicinity of Oakland its position is indicated by a trough among the lower hills two or three miles back from the piedmont plain. At Haywards it coincides with the western base of the hills, and at Irvington, with the western base of a projecting spur. In Berkeley also its line follows the base of the hills, but a little northward it climbs to the summit of the first ridge. The principal fault occasioning the earthquake of 1868 was in this rift belt, running from Haywards southward, and it is probable that some of the earlier recorded earthquakes were associated with the same belt. The fault of 1868 is described, and the rift belt is mentioned, in the "Report of the California Earthquake Commission," Vol. I., Part II., pp. 434-5 and 447.

ing, and the two types, which with present knowledge are apparently distinct, will doubtless eventually be found to intergrade. The features of the San Andreas rift—the one associated with the San Francisco earthquake—were neither created nor greatly modified at the time of that shock, but such modifications as were made were of such character as to accentuate and perpetuate the peculiarities of the belt. The belt itself would be the natural result of a long series of such events, succeeding one another with such rapidity as to dominate minor aqueous agencies in the modeling of the surface. These considerations, together with the fact that earthquakes are known to have repeatedly originated in the rift belts of California, serve to establish the rift topography as a criterion for the recognition of malloseismic districts.

Geologic Formation.—Fault scarps and rift belts serve to indicate some of the foci of past and future earthquakes. Other foci lie wholly within the earth's crust. Whether the rupture occurs above or below, its jar is propagated through the crust in all directions and affects a large area of the surface. Within this area the intensity of the shock varies primarily with distance from the origin, but it varies also with the character of the geologic formation at the point of emergence. The variation with formation has less range than the variation with distance, but is not less important to the resident and the sojourner, the architect and the engineer—that is to say, it is equally important in forecasting areas of dangerous energy. The portion of San Francisco most intensely racked by the shock of 1906 stood farther from the fault line than the portion least affected, but it stood on less coherent soil. Wood has carefully mapped the distribution of intensity in the San Francisco peninsula, as evidenced by the injury to

buildings, and shown its close correlation with the distribution of underlying material;⁴ and similar, though less detailed, correlations have been made in other regions. On the theoretic side the subject is almost untouched, and there is great need of experimentation, but the empiric results already available have much practical value and enable the geologist and engineer to distinguish broadly, within the limits of a malloseismic district, the tracts more likely, and the tracts less likely, to be affected disastrously by the passing earthquake wave.

On the whole that factor of earthquake forecast which consists in the indication of locality is in a satisfactory⁵ condition. In long inhabited regions experience designates certain districts as malloseismic. Newly settled regions may be classified, provisionally and less perfectly, by the data of physiography. And malloseismic districts will eventually be subdivided with confidence by means of geologic criteria.

TIME

Turning now to the time factor in forecasting, and retaining the point of view which emphasizes the element of danger, let us inquire what methods are available for the prediction of the time of occurrence of a destructive earthquake at a given locality or in a given district. Rational attempts to solve this problem have been connected (1) with the idea of rhythm, (2) with that of alternation, (3) with that of the trigger or starter, and (4) with that of the prelude; and each of these lines of approach is worthy of examination.

Rhythm.—Because we are surrounded by and immersed in the rhythms of art and nature, and because the earthquake is

⁴“Report of the California Earthquake Commission,” Vol. I., Part II., pp. 220–45, and atlas, maps 17–19.

a recurrent phenomenon, it is easy to infer that the interval between the last shock and the next will be similar to that between the last and its predecessor. Reasoning of this general tenor probably underlies the greater number of lay forecasts, and is in particular responsible for the wide-spread popular belief that a place recently devastated is *ipso facto* immune for several decades, or at least for several years. A similar belief prevalent among men of science has a slightly different origin, but is even more strongly held; and there is little exaggeration in saying that our guild recognize it is a duty, when the terror-stricken inhabitants of a racked and ruined city seek safety in the open spaces, to assure them that the danger is past and urge them to return to their homes. Now, it is not at all true that either the great shocks or the small shocks affecting a particular locality, or affecting a district, or affecting the earth as a whole, are separated one from another by regular or approximately regular intervals; and it is not at all true that immediate danger is past when a great shock has wrought its havoc; and yet I am prone to believe that the rhythmic principle does hold place in the mechanics of earthquakes. On that point something further will be said, but I shall first invite your attention to the general phenomena of earthquake sequence, selecting examples from the American record because we are most interested in the phenomena of our own territory.

The United States has one well-known malloseismic district, a district including central and southern California, with areas in Mexico and the Pacific Ocean, and possibly extending northward. Alaska also contains a district, and there may be a third in Utah. Since the beginning of the last century, Alaska has experienced at least nine shocks of destructive rank; but the record is fragmentary and may

omit more than it includes. For the California district eleven are listed, within the same period, the record being somewhat vague, and possibly incomplete, for the first half of the century. To these we may tentatively add the Oregon or Klamath earthquake of 1867 and the Sonora and Arizona earthquake of 1887, raising the number to thirteen. In other parts of the United States were the New Madrid (1811-12), the Charleston (1886), and a relatively weak but probably destructive shock in the New Madrid region in 1865.

The average interval between the individuals of the California series was nine years, and the separate intervals, in order, were: 12, 24, 3, 18, 8, 2, 1, 4, 15, 5, 6 and 8 years. As the centers of disturbance were scattered through the whole district and the areas of dangerous violence were of moderate dimensions, the danger record for any single locality was smaller, and the intervals correspondingly larger. In San Francisco, for instance, the last five destructive shocks have been separated by intervals of 26, 3, 30 and 8 years.

While it is manifest at once that neither of these sequences constitutes a rhythm, it is quite conceivable that they represent in some way a system of rhythms. They might, for example, be composed of several independent rhythms, each beating with its own period; or they might contain imperfectly recorded rhythms, each requiring for its interpretation some of the less violent shocks not included in the destructive class. And if it were possible to group the shocks according to place of origin, it might be found that each earthquake center has its orderly law of sequence. But while the existence of such a systematic arrangement seems within the range of possibility, I regard it as altogether outside the field of probability; and I feel sure that any attempt to discriminate rhythmic series on numerical

grounds, without any other basis for classification, would prove unprofitable.

The single element of order which unquestionably belongs to the sequence of quakings is implied by the term after-shock. Every great shock is followed by a train of minor shocks, the length of the train being roughly proportional to the magnitude of the initial shock, and the average strength and frequency of the shocks diminishing with the lapse of time. Usually also the great shock is preceded by faint tremors, or by a few small shocks. The prelude, the great shock and the train of after-shocks, together constitute a typical seismic event, and if their sequence could be absolutely depended on, the terror of the great shock might rationally be palliated by the thought that the worst is over. But unfortunately there are exceptions, and the character of the exceptions is not reassuring. Occasionally the prelude includes a shock of great power, and occasionally the train of after-shocks, instead of being wholly subordinate in intensity, includes one or more major shocks, rivaling the initial shock in violence. Of the twenty-five American examples fourteen were normal and two abnormal, the others remaining unclassified because too little is known of them. It is possibly significant that the two abnormal earthquakes were of exceptional power, the New Madrid heading the list for the United States, and the Yakutat, of Alaska, being of the same order of magnitude. The New Madrid event began with a shock of great violence at 2 o'clock on the morning of December 16, 1811, and this was followed by a long series of vigorous after-shocks, among which eight were noted as of special strength and three were reported as equaling or exceeding the initial shock. Of the last-mentioned, one followed the initial shock after an interval of five hours, and

the others severally after 38 and 53 days.⁵ The Yakutat series began with a strong shock September 3, 1899, "and there were shocks at intervals until September 10, when, at 9:20 A.M., they began to be alarming. There were fifty-two shocks, culminating in one of great violence at 3 P.M. . . . There was another violent earthquake September 15 and other shocks until September 20."⁶

In view of these facts the promptings of terror when a great shock comes may well be seconded by the admonitions of wisdom, for even though it be probable that the worst is over, a substantial possibility remains that the worst is still to come. American experience suggests that as often as one time in eight a powerful shock, instead of being the climax of the earthquake, may be only the forerunner of the climax; and when life and limb are at stake the odds of seven to one in favor of safety form but a slender basis for mental serenity.

Turning now from the statistics of sequence to the question of underlying causes, I wish to present a conception of earthquake mechanism which has developed gradually during the study of California phenomena. The block movements associated with earthquakes in California are dominantly horizontal, and the fault planes along which the blocks slide are vertical. For this reason my mental picture of the system of faults (habitually drawn with two dimensions only) is a map instead of a section on a vertical plane. Imagine a large tract of the earth's crust superficially divided by faults into acute-angled blocks, which have a prevailing trend in one direction. In composition the blocks are heterogeneous, in-

⁵MS. of report on New Madrid earthquake by M. L. Fuller.

⁶"Recent Changes of Level in the Yakutat Bay Region," by R. S. Tarr and Lawrence Martin, *Bulletin Geol. Soc. Amer.*, Vol. XVII., p. 31.

cluding stratified, metamorphic and igneous rocks, with complicated structure. The fault surfaces are not mathematically plane, but gently undulate, so that movement among the blocks involves more or less distortion of the blocks themselves. Imagine also that the tract is subject to external horizontal force of such nature as to induce internal shearing strains and the associated shearing stresses; and that the application of external force is continuous, making the internal stress cumulative. The internal stress is not uniformly distributed, because the more plastic rocks relieve the strain by flowage. When the stress along some part of a fault surface becomes greater than the adhesive force a slip occurs. When the stress within an elastic rock becomes greater than the shearing strength fracture takes place. In either case there is an instantaneous redistribution of stress. Relief of stress in the rock adjacent to the rupture is accompanied by increase of stress about the edges of the surface of parting, with the result that the area of the parting grows; and the growth is continued until regions of small stress are reached. The magnitude of the resulting earthquake depends chiefly on the quality of energy released by the relief of accumulated strain and stress.

If the quantities are large there are important after-effects. The discharge of strain causes a new arrangement of strains and stresses through a large tract; this leads to flowage and the local concentration of stress, especially in the more elastic rock; and this in turn causes fractures, of which the surface manifestations are after-shocks.

When finally equilibrium is restored, and the train of after-shocks is complete, the system of stresses, not only in the immediate neighborhood of the fault, but throughout an extensive tract, is mater-

ially different from what it was before the earthquake. In places, and especially near the fault, the general stress is less; in other places it is greater. The region of maximum stress is ordinarily shifted, so that when stresses imposed by external force again overtax the resistance, the new point of yielding is at some distance from the last.

In view of the complexity of the conditions and the intricacy of the interaction among strains, it is not to be supposed that the status at any one epoch will ever be exactly repeated. Nevertheless, its main features may recur, and whenever they do a cycle will have been completed. Such a cycle, however, would be indefinitely long, and would be too difficult of discovery to be available for purposes of forecast.

It is conceivable also that in some limited portions of the general district the local conditions may give rise to repetitive collapses somewhat independent of the general progress of events. In such case the successive earthquakes would originate in the same place and their systematic character could be recognized through that fact.

There is a class of natural and artificial rhythms in which energy gradually passes into the potential form as internal stress and strain and is thus stored until a resistance of fixed amount is overcome, when a catastrophic discharge of energy takes place. The supply of energy being continuous and uniform, the discharges recur with regular intervals. The frictional machine for generating electric sparks in the laboratory is the type; other examples are the geyser, water gurgling from a bottle, and the alternate adhesion and release of the violin bow in contact with the string. The earthquake is a repetitive catastrophe belonging to the same mechanical group, and if its mechanism were as

simple as that of the electric machine its rhythm would be as perfect. If the stresses of an earthquake district affected only homogeneous rock and were always relieved by slipping on the same fault plane, the cycle of events would be regular; but with complexity of structure and multiplicity of alternative points of collapse, all superficial indication of rhythm is lost. If rhythmic order shall ever be found in the apparent confusion, it will be through an analysis which takes account of the points of origin of all important shocks.

Alternation.—The principle of alternation in the occurrence of earthquakes has already been touched. When a large amount of stored energy has been discharged in the production of a great earthquake and its after-shocks, it would seem theoretically that the next great seismic event in the same seismic district was more likely to occur at some other place, and that successive great events would be distributed with a sort of alternation through the district. This hypothesis I used twenty-five years ago, in predicting that the next slip on the fault at the base of the Wasatch range, instead of occurring in the locality of the last previous slip, would take place at a different point; and it has been more recently applied by Omori, Hayes and Lawson in forecasting earthquakes on the western coast of the two Americas. These geographers agree in regarding the entire coast either as a single seismic district or as a portion of a greater district, in which there is interdependence of parts. Omori pointed out that in the period of six years from 1899 to 1905 there were extensive disturbances in Alaska, Mexico, Central America, Colombia and Ecuador; stated that the gap thus left between Alaska and Mexico had led him to anticipate an early

' Monograph I., U. S. Geological Survey, p. 362.

rupture in that tract of coast; and suggested, after his first anticipation had been realized by the San Francisco earthquake, that the next disturbance might be south of the equator—where the Valparaiso earthquake soon afterward occurred.*

*In an interview published by the San Francisco *Bulletin* of June 13, 1906, F. Omori says: "Between 1899 and January 1 of this year (1906) there have been several extensive earthquakes along the coast of Alaska, Mexico, Central America, Colombia and Ecuador. These disturbances are not to be regarded as separate or unconnected phenomena, but were the result of great stress which was taking place all along the west coast of North and South America. The Pacific slope of the United States remained comparatively quiet all this time, so it was most natural to expect a continuation of the disturbance in these parts.

"As it has finally happened this time I believe it is over and the adjustment complete. . . .

"The center of a future earthquake, due perhaps to the same causes as this, will probably be different, and may take place as far away as the other side of the equator."

In a bulletin of the Imperial Earthquake Investigation Committee of Japan, published in January, 1907, Vol. I., pp. 21 and 23, he continues the subject, illustrating the distribution of seismic disturbances by a map, and concludes thus:

"The great stresses going on along the whole Pacific coast of America, which thus resulted in the occurrence of a series of great earthquakes, seem to be connected with the growth of the Rocky and Andes mountain ranges; the Valparaiso earthquake bringing probably the great seismic activity along the zone under consideration for the time to an end."

The forecast of an earthquake between Alaska and Mexico was verified by the California shock of 1906 and the forecast of a disturbance south of the equator by the Valparaiso earthquake of 1906. The forecast of immunity for some decades in the Mexico-Central America group was shown to be erroneous by the Mexican earthquake of 1907. The success or failure of the prediction of immunity for other parts of the coast remains to be determined. It is to be noted (1) that the Mexican earthquake, occurring in a district for which Omori predicted immunity, was forecast by both Hayes and Lawson; (2) that Lawson forecasts disturbance in a region north of California

Hayes, after the San Francisco and Valparaiso earthquakes, suggested Mexico as a probable locality for the next rupture; and after the earthquake which devastated the state of Guerrero in southern Mexico, made a similar suggestion as to Colombia.*

for which Omori forecasts immunity, and that Hayes forecasts disturbance for a region south of Mexico for which Omori forecasts immunity. See the following notes.

*C. W. Hayes is thus reported in the *Washington Times* of April 16, 1907:

"At least one man, who has studied seismic disturbances, has succeeded in predicting the locality of an earthquake months before the shock occurred.

"He is Dr. Charles Willard Hayes, of the United States Geological Survey, who made a report for the government on seismic conditions in Nicaragua in 1899. In this report he made the statement after the recent destructive earthquake at Valparaiso that he would not be surprised if the next section of the American continent to be visited by a seismic disturbance would be somewhere between San Francisco and Valparaiso, probably in Mexico.

"Dr. Hayes would not be surprised if the next earthquake should occur in the United States of Colombia, South America.

"In speaking of the earthquake in Mexico yesterday Dr. Hayes said to a *Times* reporter this morning:

"While it is impossible to predict with any accuracy the location and time of the occurrence of an earthquake, our knowledge of the geological structure of the earth enables us to determine within certain limits the probable areas where seismic disturbances are most likely to occur. The course of these disturbances may be expected to follow a general line of adjustment of the earth's crust along the western slope of the two American continents, the line being somewhat broken in Central America.

"The course from South America extends north to the islands in the Caribbean Sea, and that from North America is traceable down through Mexico and Central America. This course extends north along the coast of Alaska across the Aleutian Islands, down the Siberian coast, through Japan and thence across the Indian Ocean.

"The disturbance in Alaska a few years ago was the first of the series that has afflicted the western hemisphere recently. It was natural to

Lawson mentioned breaks in the continuity of recent demonstrations, between the southern part of California and Central America, and between the northern part of California and Alaska, and suggested the probability of early visitations in Mexico and the Oregon-Washington region. In this forecast he anticipated by a few weeks the Guerrero earthquake.¹⁰ Omori went farther and expressed the opinion that the Valparaiso earthquake was the final term of a series, and that the whole Pacific coast of America would be exempt for a time expect the next one at some distance, and, as it happened, this occurred at San Francisco. Then the Valparaiso disturbance being so far to the south it was probable that the next shake would be somewhere between the two. The shock at Jamaica was probably connected with the Valparaiso earthquake, being in the same course with it. That in Mexico is more likely to be connected with the course of disturbance from Alaska down.

"Dr. Hayes, when asked if he would venture to predict the locality in which the next earthquake might occur, said that he did not wish to go on record as making any prediction on a matter concerning which scientific knowledge was so limited, but was of opinion that it would not be unreasonable to look for one in northern South America in the United States of Colombia. Asked whether a disturbance there would be likely to affect the region of the Panama canal, he thought that Panama might feel tremors from a considerable shock, but that it was unlikely any damage would result."

¹⁰A. C. Lawson, in a lecture read to the National Geographic Society, March 29, 1907, attributed the California earthquake to a series of ruptures that had been traveling along the western coast of America. "So far it has occurred everywhere along the coast except in a stretch between the southern part of California and Central America and an area between the northern part of California and the southern part of Alaska. These stretches, I believe, will be visited before long and then the long line of this earthquake will be complete from Chili to Alaska." This statement preceded by a few weeks the occurrence of the Guerrero earthquake in Mexico, and its prognostication was thus promptly verified as to the district south of California. It awaits verification for the district north of California.

from *great* seismic activity. He expected for San Francisco a period of immunity of thirty to fifty years and for coastal regions from Alaska to Ecuador of twenty to thirty years.

It will be observed that this idea of a series, breaking on the American coast in the course of a few years, and followed by a comparatively long interval before the arrival of another series, an idea apparently shared by Hayes and Lawson, combines rhythm with alternation in the theory of forecasting.

Prediction and verification are the test of hypothesis, and this group of predictions—albeit tentative and advanced with judicious caution—embodying, as they do, the diverse views of independent investigators, who approach the subject from both seismologic and geologic sides, constitute a valuable contribution to seismic forecasting. The outcome in verification will have bearing not only on theories of alternation, rhythm and rhythmic immunity, but on the order of magnitude of the seismic district within which effective mechanical interaction takes place, and also on the profounder earth problems with which the question of the ultimate cause or causes of earthquakes is involved. If it shall appear as highly probable that yieldings to crustal stress in remote parts of North America have a direct influence on the dates of similar events in South America, the primary sources of the stresses can hardly be of such local nature as the shifting of load through degradation and aggradation or the outward flow of continental excess of matter, but should be sought rather in forces tending to deform the planet as a whole.

Trigger.—The third general principle applicable to prediction is that of the trigger—or the principle involved in the parable of the last straw, which broke the camel's back. As the growing earth stress

little by little approaches the limit of the resisting force there is a critical period during which a relatively small additional stress arising from some other source may precipitate the catastrophe. A number of possible sources for the additional stress are known, the influence of several has been fairly demonstrated in a statistical way, and it is on the whole probable that a large majority of earthquakes owe their precise dates to such contributory causes. Many of the precipitating factors are periodic in their character, and the times of their maxima, or other favorable phases, are known; so that, granting their influence, they serve to restrict prediction to certain epochs. They are not of primary importance in forecasting, but when the approximate date of a future earthquake shall have been learned by other means, they will serve to refine the estimate of time.

The principal known causes of periodic variation of stress are bodily tides of the earth; oceanic tides, which alternately load and unload the sea bed near the shore; the winter load of snow on parts of the land; annual and diurnal variations of atmospheric pressure; diurnal variations of barometric gradient; and the wandering of the earth's axis of rotation. The relative importance of the several influences can not yet be indicated, but it is known that their absolute importance is not the same in all places. Three belong to the coastal belts, two to the land; and two belong to land and sea, but vary with latitude. Their relative importance in any particular locality may depend also on the direction of the slowly growing tectonic stress of the crust; for in order to be effective the temporary or adventitious stresses must be of such character as to augment the tectonic stresses. Let me illustrate this point.

The tidal sway of an oceanic basin

raises and lowers the surface very little where the water is deep, but has a much greater effect on the shoals bordering coasts. The strip of sea bed following the coast is subjected twice a day to the addition of a heavy load of water, and in the intervening hours is relieved of pressure by the same amount. On the seaward side of the strip there is a gradual change in pressure, and on the landward side, just at the water edge, an abrupt change; and these pressure differences cause strains and stresses in the crust beneath. The directions of the induced strains lie in vertical planes at right angles to the coast, and are competent to increase or diminish tectonic stresses having similar directions. On the coast of Alaska near Mt. St. Elias the tectonic changes in progress include an uplift of mountains parallel to the coast, and the main tectonic stresses may be assumed to lie in vertical planes normal to the coast; so that here the oceanic tides are competent to precipitate earthquakes. But on the California coast near San Francisco, where the directions of the main tectonic stresses are horizontal and are approximately parallel to the coast, the stresses from oceanic tides may be ineffective. On the other hand the stresses created in the crust by the shifting of the axis of rotation are probably better calculated to augment tectonic stresses at San Francisco than at Mt. St. Elias.

Unfortunately the value to the forecaster of the periodic stresses is impaired by the occurrence of other transient stresses which are not periodic. The barometric gradients and extremes of pressure connected with cyclonic storms are of this class, and so are the pressure changes arising when the sea is pushed against the land or drawn from it by strong wind; and all these storm effects are at times much greater than the rhythmic changes of cor-

responding character. If storms are really earthquake-breeders—instead of the traditional calm, sultry, so-called “earthquake weather”—then the shocks they precipitate can be foretold only so long in advance as the storms themselves are fore-known.

The most potent of all precipitants of earthquakes is also useless to the fore-caster because its action is unforeseen. It is the earthquake wave emanating from a nearby focus. The response to such an impulse follows the initial shock so closely that the two shocks are combined in a single seismic event—an earthquake with two foci, or a “double-earthquake.”

Prelude.—The forecasting of earthquakes by means of prelude has nothing in common with other methods, but resembles rather the forecasting of the weather for the day by a glance at the sky in the morning. It depends on the recognition of premonitory signs, and also, to some extent, on the recognition of the earliest phases of the event itself.

When a fracture or other parting of the rock takes place, the jar which is communicated to surrounding portions of the crust is not a simple impulse, but a congeries of vibrations differing in amplitude and period, and in speed of transmission. At any point of the focus they begin together, but traveling through the rock at different rates, they arrive at any distant point at different times; and the greater the distance the greater their separation. The strongest of the vibrations, or those said to constitute the principal shock, are not the first to arrive, but are preceded by vibrations which are much weaker, and are known as the preliminary tremors. At a point twenty miles from the origin the preliminary tremors are felt four or five seconds before the principal shock. There are also vibrations too minute to be felt, and not yet recorded by

the most delicate seismographs, but of such frequency that they fall within the register of the ear and are perceived as sounds, and these usually begin to arrive before the preliminary tremors. The sounds and faint tremors are notes of warning, and to him who not only hears and feels but understands they give command of precious seconds. People who live in earthquake countries and are familiar with these warnings acquire the habit of instantly taking precautionary measures.

Still earlier than the sounds and tremors with which the earthquake begins, are sometimes sounds, tremors or minor shocks, and it is suspected that phenomena of this sort may betray growing seismic activity and thus constitute premonitory symptoms of the final rupture. Little is known of them in any exact way, because they occur at a time when attention is not directed to such matters; and nearly all records are made from memory after the occurrence of the earthquake. If they are veritable preludes, connected in a systematic way with the mechanics of the earthquake, they are probably analogous to the cracklings and crepitations observed in strained beams and strained blocks of rock before collapse occurs. With reference to the possibilities of forecasting, expectation centers especially on faint tremors such as are occasionally perceived a few minutes or a few hours before an earthquake shock. They are more frequently inferred from the peculiar behavior of animals; and after making much allowance for the influence of imagination on the memory of observers, there is still reason to think that various animals are affected by vibrations to which man is insensible, and that their reported uneasiness before earthquake shocks is real and is occasioned by premonitory vibrations.

The scientific study of preludes belongs

to the future, and especially to such adaptations of seismographic appliances and methods as we may confidently anticipate. Feeble tremors, ascribed to minute crepitations of the crust, have already been made audible by means of the microphone, so that the ear could be applied to a sort of seismic stethoscope; and the next step will perhaps be to construct a seismograph of such delicacy as to record these minute vibrations, and install it where it will be undisturbed by tremors of artificial origin.

RÉSUMÉ

Summarizing briefly, many of the malloseismic districts or areas of earthquake danger are known from records of past experience, and others are being recognized by physiographic characters. Within them are tracts of special instability because of the incoherence of the underlying formation, and these can be both characterized in general terms and locally mapped. The general relations of danger to place are so well understood that an early solution of their outstanding problems may be assumed. Of the relations of danger to time much less is known and there is less promise for the immediate future. The hypothesis of rhythmic recurrence has no sure support from observation, and is not in working order for either large or small areas. Its corollary of local immunity after local disaster is more alluring than safe. The allied hypothesis of alternation between parts of a district is being tested by a great example, but the verdict belongs to the future. The hypothesis of precipitation by accessory forces which are in large part periodic and foreknown, has a good status and is being developed on the statistical side. It promises to make the date of prediction more precise if ever the approximate time shall be achieved by other

means. The hypothesis of an intelligible prelude has barely been broached and the means to test it are not yet in sight. In a word the determination of danger districts and danger spots belongs to the past, the present and the near future; the determination of times of danger belongs to the indefinite future. The one lies largely within the domain of accomplishment; the other still lingers in that of endeavor and hope.

We may congratulate ourselves that it is not the place factor which lags behind, for knowledge of place has far more practical value than knowledge of time. In fact I see little practical value in any quality of time precision attainable along lines of achievement now seen to be open. Suppose, for example, that a prediction based on rhythm or alternation should indicate an earthquake as due in a certain year, and that tides should be recognized as the most potent accessory cause; then for several days each month, and possibly for many months, expectation would be tense, and the cost in anticipatory terror would be great. Or suppose that prelude phenomena should be found to afford real warning; the forecaster on duty would still have to deal in probabilities, and when in doubt would often sound vain warnings, in the conscientious effort to escape the greater error of omission at the critical time—and again nervous strain would be wasted. And even if warning were definite, timely and infallible, so that peril of life could be altogether avoided, property peril would still remain unless construction had been earthquake-proof. If, on the other hand, the places of peril are definitely known, even though the dates are indefinite, wise construction will take all necessary precautions, and the earthquake-proof house not only will insure itself but will practically insure its inmates.

MORAL

It remains to draw the moral. In view of these facts as to forecasting, and of the further fact that we have in our land a district subject to strong earthquakes, there are duties to be recognized and policies to be advocated. It is the duty of investigators—of seismologists, geologists and scientific engineers—to develop the theory of local danger spots, to discover the foci of recurrent shocks, to develop the theory of earthquake-proof construction. It is the duty of engineers and architects so to adjust construction to the character of the ground that safety shall be secured. It should be the policy of communities in the earthquake district to recognize the danger and make provision against it.

The general fact of local danger spots, where the agitation during strong earthquakes is peculiarly violent, has long been familiar. It is known that they are commonly found in lowlands where the underlying formation is a deep deposit of alluvium or other unconsolidated material, and that such material, while it aggravates great shocks, absorbs and quenches small ones. It is also known that the local phenomena are in some way connected with the transformation of earthquake waves in passing from elastic to inelastic material. But a mechanical theory of the phenomena is yet to be supplied. For economic, as well as scientific purposes, this is one of the important fields for investigation. In Japan, where earthquakes are much more frequent than in any portion of our own land, the subject has been studied and may still advantageously be studied, by the observation of natural shocks. In America the problem can be more readily studied by means of artificial earthquakes in the laboratory, continuing the line of experimentation begun by

Rogers.¹¹ When the underlying principles have become known, it will be comparatively easy for geologists, engineers and architects to estimate the danger factor in places to be occupied by buildings.

The San Andreas rift,¹² now traced through so much of its length as traverses inhabited areas, is recognized as a danger belt of a peculiar character, to be avoided especially by water conduits and railways. Although it is probably the most extensive rift belt in the country, it is not the only one, and the positions of all others should be determined and mapped. The foci or epicenters of recurrent earthquakes are also localities of special danger, even though the underlying formation is firm and elastic. So far as the earthquake faults reach the surface of the ground, the epicentral tracts coincide with the rift belts and fault scarps; but some of the foci are doubtless wholly subterranean and need for their discovery a seismic survey like those conducted in Japan, Italy, England and, since the Valparaiso earthquake, in Chili. In Japan, which now takes first place in the study of earthquakes, the survey is conducted by a system of seismographic observatories in cooperation with a large body of local correspondents—a mode of organization quite analogous to that of our Weather Bureau, with its system of thoroughly equipped stations and its wide-spread corps of volunteer observers.

Much progress has already been made

¹¹ Professor F. J. Rogers, of Stanford University, gave harmonic motion in a horizontal direction to a box of sand, and found that under certain conditions a body resting on the sand received motion which was not harmonic, and which had greater amplitude and a much greater maximum acceleration than the motion of the box. His experiments are described in the "Report of the California Earthquake Commission," Vol. I., Part II., pp. 326-35.

¹² "The California Earthquake Investigation Commission," Vol. I., Part II., pp. 25-53.

in determining the principles of earthquake-proof construction. After each great earthquake which in modern times has devastated a city, there has been engineering study of the buildings which successfully resisted the vibrations and of those which succumbed, so that the construction of the future might profit by the experience of the past. In various countries, and especially in Japan, there have been series of experiments either for determining the mechanical character of earthquake shocks, or for testing the ability of different types of construction to withstand them. The results of these observations and experiments have helped to determine the building regulations and building methods in various earthquake districts. For our own purposes there are needed, not merely a complication of the principles developed elsewhere and of the deductions from recent experience in California, but special lines of investigation, covering, theoretically and experimentally, the materials and architectural methods employed in this country at the present time. In the line of experiment, we may well follow the example of our oriental neighbors, by constructing a machine which will give to a platform all the motions characteristic of a violent earthquake, and using the platform as a testing ground for types and materials of construction.

The proposition that it should be the policy of the inhabitants of an earthquake district to recognize the danger and make provision for it appears self-evident, but I regret to say that its soundness is not universally recognized in California. As long ago as 1868, Whitney, speaking of the Pacific states, said:

The prevailing tone in that region, at present, is that of assumed indifference to the dangers of earthquake calamities—the author of a voluminous work on California, recently published in San Francisco, even going so far as to speak of earthquakes as “harmless disturbances.” But earth-

quakes are not to be bluffed off. They will come, and will do a great deal of damage. The question is, How far can science mitigate the attendant evils, and thus do something toward giving that feeling of security which is necessary for the full development of that part of the country.¹³

This policy of assumed indifference, which is probably not shared by any other earthquake district in the world, has continued to the present time and is accompanied by a policy of concealment. It is feared that if the ground of California has a reputation for instability, the flow of immigration will be checked, capital will go elsewhere, and business activity will be impaired. Under the influence of this fear, a scientific report on the earthquake of 1868 was suppressed.¹⁴ When the organization of the Seismological Society was under consideration, there were business men who discouraged the idea, because it would give undesirable publicity to the subject of earthquakes. Pains are taken to speak of the disaster of 1906 as a conflagration, and so far as possible the fact is ignored that the conflagration was caused, and its extinguishment prevented, by injuries due to the earthquake. During the period of after-shocks, it was the common practise of the San Francisco dailies to publish telegraphic accounts of small tremors perceived in the eastern part of the United States, but omit mention of stronger shocks in the city itself; and I was soberly informed by a resident of the city that the greater number of the shocks at that time were occasioned by explosions of dynamite in the neighborhood. The desire to ignore the earthquake danger has not altogether prevented the legitimate influence of the catastrophe on building regulations and building practises, but

¹³“Earthquakes,” by J. D. Whitney, *North American Review* for April, 1869, Vol. CVIII., p. 608.

¹⁴“California State Earthquake Investigation Commission,” Vol. I., Part II., p. 434.

there can be little question that it has encouraged unwise construction, not only in San Francisco but in other parts of the mallo seismic district.

The policy of concealment is vain, because it does not conceal. It reflects a standard of commercial morality which is being rapidly superseded, for the successful salesman to-day is he who represents his goods fairly and frankly. It is unprofitable, because it interferes with measures of protection against a danger which is real and important.

To understand the practical importance of the earthquake danger, let us for a moment consider it from the insurance point of view. To determine rate of premium, an insurance company first computes the risk, and this computation is based on past experience, comparing the actual losses with the amount exposed to loss. We know, with fair approximation, the loss of life by earthquake in California from the year 1800, and can compare it with the population. As to the property loss, our knowledge is relatively indefinite, but it suffices for the present purpose.

Consider first the value of insurance against the danger of death by earthquake. Seven hundred and nine deaths are reported to have been caused by the San Francisco earthquake, and about 76 deaths by earlier earthquakes, making a total of 785.¹⁵ The total annual population for the same period, that is to say, the sum of the populations for the several years, was about 51,500,000.¹⁶ Using these data, the

¹⁵ The casualties in 1906 are given as reported by the State Board of Health; those in earlier years were compiled from Holden's "Catalogue of Earthquakes on the Pacific Coast, 1769 to 1897."

¹⁶ To obtain this figure the populations of the state on census years were platted on section paper and a curve of population drawn through them, thus graphically interpolating estimates for intervening years. For years earlier than 1850

annual premium on a policy for \$1,000, payable only in the event of death by earthquake, is computed at one cent and a half, plus the cost of doing the business and the profit of the company. The minuteness of the earthquake risk may be further indicated by saying that it is one tenth of the risk of death by measles. If a timid citizen of California should emigrate in order to escape the peril from earthquake, he would incur, during his journey, a peril at least two hundred times as great, whether he traveled by steamship, sailing vessel, railway car, motor car, stage, private carriage, or saddle; and if in emigrating he removed from San Francisco to Washington City he would incur, by change in environment as regards typhoid fever, an increment of peril eighteen times as great as the earthquake peril he escaped.¹⁷

The danger to property is much more serious. Using the same method of computation as before, and availing myself of the expert knowledge of local statisticians, I have made a parallel estimate of the earthquake risk to buildings in California, and find it to be about five hundred times as great as the risk to life. If a company were to undertake the insurance of buildings against injury by earthquake, and base its premium on the experience of the state from 1800 to 1908, the average premium on a policy of \$1,000 would be about \$7, plus the cost of doing the business. Estimates were based on data contained in Hittell's "History of California." The census returns do not include Indians. In making estimates of the population previous to 1850 the Mission Indians were included. The estimate includes the year 1908.

¹⁷ The U. S. Census returns for the years 1901-5 give the following death rates, per 100,000, from typhoid: San Francisco, 27.0; Washington, 58.6. The statement in the text of course applies only to the risk of death from typhoid; the death rate from all causes was higher, in the same years, in the western city than the eastern.

ness.¹⁸ This is nearly twice as large as a similar figure expressing the fire risk for the United States, as based on the accumulated experience of underwriters. Just as in the case of fire insurance, the premium on earthquake insurance would be adjusted to the local conditions; it would be higher for houses on soft ground than for those on bed rock, relatively high for houses near known earthquake foci, and very low for houses classed as earthquake-proof.

In making this estimate the fire damage occasioned by the earthquake damage of 1906 was treated as part of the earthquake damage. Had the direct earthquake damage alone been considered, the compu-

¹⁸In assembling data for this estimate I was greatly assisted by Professors C. C. Plehn and A. W. Whitney, of the University of California, but these gentlemen are not to be held responsible for the estimate itself. The estimate involves, among others, the following assumptions: (1) in that part of San Francisco burned over in April, 1906, the loss from destruction and injury of buildings amounted to one third the entire loss; (2) the ratio of sound value to assessed value of buildings in San Francisco in 1905 was 1.7; (3) the similar ratio for the entire state was 2.0; (4) the average value of buildings per capita in California was the same for the entire period 1800-1908 as for the single year 1905. Some of the elements of the estimate are as follows:

Damage to buildings in burned district of San Francisco in 1906 (= $\frac{1}{3} \times \$350,000,000$)	\$117,000,000
Damage to buildings in San Francisco, outside burned district, 1906	7,000,000
Damage to buildings outside of San Francisco, 1906	15,000,000
Damage to buildings in California, 1800-1905	20,000,000
Total earthquake damage to buildings in California, 1800-1908	\$159,000,000
Total corresponding "exposure" (=sum of annual value of buildings in California 1800-1908)	\$22,000,000,000
Basal insurance factor (=ratio of total loss to total exposure)	0.00723
Risk on policy of \$1,000	\$7.23

tation would have yielded a figure materially smaller, though still comparable with the basal fire insurance factor. But there seems no good reason for excluding the fire damage, for not only was the San Francisco conflagration caused wholly by the earthquake, but fire is a frequent sequel of the wrecking of buildings by seismic shocks. Nearly all our appliances for heating, cooking and lighting are sources of fire danger when deranged by violence to the containing buildings, and if the agent of violence affects a large area, as in the case of earthquakes, the appliances for extinguishing fires are apt to be disabled at the same time.

It is possible that the estimate of the building risk is exaggerated by reason of its having been made just after the great disaster of 1906. It certainly would have been materially smaller if made by the same method just before that disaster. But this qualifying circumstance is largely if not wholly offset by the fact that various shocks of the same physical rank as that of 1906 wrought comparatively little havoc because at the time of their occurrence the areas shaken were sparsely populated—at least by house-building races. The Inyo earthquake of 1872, having its origin in Owens Valley, demolished the village of Lone Pine with a completeness not paralleled in 1906, and the falling walls crushed to death a tenth part of the village population. The shocks of 1812, affecting a tract on which Los Angeles, Santa Barbara and other large towns are now built, were limited in their destructive effect to the Spanish Missions because those were then the only houses; but the mission buildings fared badly, and it is related that thirty or forty mission Indians lost their lives. The earthquake hazard indicated by these occurrences was certainly not less than that emphasized by the recent disaster in a populous district,

and yet the absolute losses they occasioned were so small as to have little influence on the totals used in the computation.

On the whole, weighing these and other factors of the problem as well as I am able, I am disposed to adhere to the estimate, not, indeed, claiming for it a high measure of precision, but regarding it as a fair approximation to the truth, and possibly as good as may be derived from the available facts.

It is needless to carry further the discussion of insurance rates. Its purpose has been served in showing that the earthquake risk to buildings in California is comparable with the fire risk and equally worthy of serious consideration. There is no present question of earthquake insurance, of which the function would be merely to distribute earthquake losses, but there is a question of the prevention of earthquake damage.

Earthquake damage is at least as preventable as fire damage. It is possible so to construct houses that they will neither collapse nor otherwise be vitally injured by such shocks as have visited California in the past. In a house so built there will be small danger from earthquake-started fires because they will be both accessible and quickly detected. It is wreckage that prevents the prompt extinguishment of the initial blaze. In a house so built there will be little damage to furniture, merchandise and other valuable contents. With houses so built the life risk will become a vanishing quantity, for practically all earthquake casualties are directly due to the failure of buildings. And in a community thus protected in life and property the terror of the mysterious unheralded temblor—a factor far outweighing the actual personal peril—will gradually wear away.

In saying that earthquake damage is preventable I would not be understood to

imply that the subject of earthquake-proof construction is at all adequately developed. Competent modes of construction are known, but the best modes, the most economic modes, the modes best adapted to American materials and conditions remain to be determined, and there is much need of investigation.

It should be the policy of the people and state of California to see that the necessary investigations are made, and that the results are embodied in the building regulations of all cities as well as in the entire building practise of the state. And, in order that the methods of construction may be properly adjusted to the very unequal local requirements, provision should be made for a seismic survey and the mapping of tracts of special earthquake danger.

G. K. GILBERT

JEAN ALBERT GAUDRY¹

From time to time as honored chieftains fall in the front ranks of the world's intellectual forces that are making for scientific progress, and bent on the conquest of new realms of knowledge, it befits men of a younger generation to take note of the passing of these heroes, these veteran standard-bearers who now rest from their labors, leaving a splendid memorial of their lifework behind them. Upon such occasions it is well to call to mind some of the more notable achievements of these patient searchers after truth, and to bethink ourselves what manner of men were they who contributed largely to widening the bounds of human understanding, whose lives were consecrated to the service of the sovereign mistress of truth.

An occasion of this kind has recently befallen us. Geological and biological science mourn the loss of Professor Albert Gaudry, foremost of the modern school of French paleontologists, a man of remarkable and versatile talents, in-

¹ Presented before the American Society of Vertebrate Paleontologists at the Baltimore meeting, December 30, 1908.

vestigator, teacher and author of far-reaching influence, and not less distinguished as a naturalist than universally beloved for his sweet simplicity of character and attractive personality. In him were happily combined that temper of mind and delicate sensitive spirit which proclaimed him not only as a fine type of the cultured scientific gentleman, but revealed him likewise as an *homme de cœur*, rich in human sympathy. Greatly as we deplore his loss, we may be glad that such a shining exemplar has graced our science. It is pleasing to contemplate him as a naturalist and interpreter of nature, but better still as a humanist. We honor him for his devoted service, we revere him for the lofty ideals he realized as a man. Much is expressed in the title by which his pupils and colleagues scattered over two continents were wont to address him: *maître vénéré*. His predominant trait was rightly characterized in an address delivered by his successor in the museum, Professor Boule, on a memorable occasion in the spring of 1903: "L'essence de votre nature, cher maître, c'est la bonté même." All who have enjoyed the privilege of personal acquaintance with the late president of the institute will concur in that sentiment.

The main facts in the life history of Professor Gaudry are briefly told. Born at Saint-Germain-en-Laye, near Paris in 1827, eldest son of a well-known advocate, as a youth fond of natural history pursuits and amateur collector of fossils at Montmartre, awarded the degree of doctor of science at the age of twenty-five and appointed assistant professor of paleontology at the Paris Museum the following year, we find him undertaking his first serious work as a naturalist whilst engaged on a scientific mission to the Orient and islands of the *Ægean* in 1853. His first publications date from the same year, and at this time he began his long-continued and classic studies of the late Tertiary vertebrate fauna at Pikermi in Attica. The results of this work, published 1862-7, under the title of "*Animaux fossiles et géologie de l'Attique*," together with its sequel on fossil vertebrates from Mont Léberon, won for him recognition as a leader in his special field, and constitute probably his

most enduring monument in the province of descriptive paleontology. Other technical memoirs followed, among which it will suffice to mention those on *Actinodon* (1887), *Dryopithecus* (1890), pythonomorphs (1892) and Patagonian vertebrates, the last subject being one upon which he was still engaged at the time of his death, on the twenty-seventh day of November, 1908.

Excellent as are these special monographs, it is through his more popular, or at any rate less strictly technical, or perhaps we should say more broadly philosophical, writings, that Gaudry's name is most widely known both among his own countrymen and abroad. These brilliantly written essays, published in tripartite series during the years 1878-96, the first having for title "*Les Enchaînements du monde animal*," have exercised an incalculable influence in spreading evolutionary ideas and inculcating sound notions of paleozoology. It has been said that a philosopher is always something of a "*poète manqué*." This quality on the part of the author is strongly marked in the three volumes in question, and manifests itself not only in style, but in ideas, not only in the main theme under discussion, but in many a charming and naïve excursus, the effect of which is to make his work most exhilarating reading. His object is to present, as he tells us in one place, some things to instruct the mind, and yet others to satisfy the soul. And we must admit that he succeeds very well in both these aims. He was artist to this extent at least, that he sought in nature an ideal standard of truth and beauty, and made that standard effective in all human relations.

To the typical French mind, as to the ancient Greek, is commonly attributed a quick and accurate intuition, facile power of generalization, and a fondness for broad, comprehensive views as applied to any subject. Professor Gaudry well exemplified these racial characteristics. An analyst so far as involves the merely mechanical collection of facts, his genius consists in synthesis, in the rational coordination of his material after it has been laboriously brought together. In the early days of evolutionary discussion he incurred

reproach for being a *too* brilliant theorist. Time has since justified his keen sense of discrimination, his rigid intellectual candor, and subtlety in drawing right conclusions, not only in those momentous issues, but in most of his later philosophical writings. His work obviously has enduring qualities; his positive results are gained for all time, and become the heritage of science.

One further feature deserves to be pointed out. Professor Gaudry was always consistently opposed to the idea of following a scientific pursuit from primarily mercenary motives. He warns young men of the necessity of cultivating higher ideals of their chosen calling. His words seem to echo those of Francis Bacon, who long ago complained that "men have entered into a desire of learning and knowledge, sometimes as if there were sought in knowledge a shop for profit and sale; and not a rich storehouse for the glory of the Creator and the relief of man's estate." On the other hand, his career reminds us more emphatically than any precept, that in order to attain the repose and exaltation of soul that come after a lifetime of worthy effort and resources nobly expended—"it is worth while in the days of our youth to strive hard for this great discipline; to pass sleepless nights for it, to give up to it laborious days; to spurn for it present pleasures; to endure for it afflicting poverty; to wade for it through darkness, and sorrow, and contempt, as the great spirits of the world have done in all ages and all times."

Finally, no truer thing could be said of Gaudry than one of the most graceful and talented of French writers—Flaubert—said of himself: "*Je fais tout ce que je peux pour élargir continuellement ma cervelle et je travaille dans la sincérité de mon cœur; le reste ne dépend pas de moi.*"

C. R. EASTMAN

HARVARD UNIVERSITY

SCIENTIFIC NOTES AND NEWS

MR. ALEXANDER AGASSIZ and Professor Theobald Smith have been appointed delegates from

Harvard University to the Darwin Celebration at Cambridge University, England, in June, 1909.

THE Académie Royale de Médecine de Belgique, at its meeting of December 26, last, elected Dr. Charles S. Minot, of the Harvard Medical School, a foreign corresponding member of the academy.

M. P. VILLARD has been elected to succeed M. Mascart as a member of the Paris Academy of Sciences, in the section of physics.

DR. HENRY E. CRAMPTON has been appointed curator of the department of invertebrate zoology in the American Museum of Natural History, to fill the place made vacant by the resignation of Dr. William M. Wheeler. He will retain an official connection with Columbia University, where he now is professor of zoology in Barnard College. Dr. Frank E. Lutz, investigator in the Station for Experimental Evolution of the Carnegie Institution, has been appointed an assistant curator in the museum. Dr. Alexander Petrunkevitch has become officially connected with the museum as honorary curator of the Arachnida.

PRESIDENT ELIOT has purchased a house on Brattle Street, Cambridge, which he will occupy after leaving the residence provided by Harvard University for the president.

DR. H. C. CHAPMAN, professor of the institutes of medicine and medical jurisprudence at Jefferson Medical College, and for thirty-two years a member of the faculty, has resigned, his resignation to take effect in May next.

GOVERNOR GUILD, of Massachusetts, has been elected president of the American Forestry Association to succeed President Wilson.

PROFESSOR ROBERT KOCH has been elected a president of the German Central Committee for the Prevention of Tuberculosis, in the room of its founder, the late Herr Friedrich Althoff, ministerial director of the Prussian Education Office.

DR. and MRS. W. A. MURRILL are in Jamaica to study and collect fungi in the interests of the New York Botanical Garden.

PROFESSOR HIRAM BINGHAM, of Yale University, after attending the pan-American Scientific Congress that has just closed at Santiago, Chile, left for southern Peru, to engage in historical research.

LIEUTENANT BOYD ALEXANDER left England on December 12 with the object of thoroughly exploring the islands of São Thomé, Principe and Annobon, chiefly from a zoological point of view.

DR. SVEN HEDIN has visited Japan on his way home and has there received various honors, including the medal of the Japanese Geographical Society. Twenty-nine years ago the late Baron Nordenskiöld, after his accomplishment of the northeast passage, received from the society its medal, and a similar medal was afterwards awarded to General Fukushima for his ride through Siberia. Dr. Hedin, it seems, is only the third who has received this medal, and the only two foreigners who have been awarded this honor are Swedes.

At the meeting of the College of Physicians, Philadelphia, on January 6, the following officers were elected: *President*, Dr. James Tyson; *Vice-president*, Dr. G. E. de Schweinitz; *Censors*, Dr. Richard A. Cleeman, Dr. S. Weir Mitchell, Dr. Louis Starr and Dr. Arthur M. V. Moigs; *Secretary*, Dr. Thomas R. Neilson; *Treasurer*, Dr. Richard H. Harte.

At the December meeting of the St. Louis Chemical Society, the following officers were elected for the ensuing year: *President*, H. E. Wiedemann; *Vice-president*, C. J. Borgmeyer; *Recording Secretary*, Geo. Lang, Jr.; *Corresponding Secretary*, J. J. Kessler; *Treasurer*, A. A. Kleinschmidt; *Councilors*, C. E. Caspari and Leo Suppan.

DR. HENRY PRENTISS ARMSBY, director of the Institute of Animal Nutrition of the Pennsylvania State College, delivered a course of four lectures on the Principles of Animal Nutrition at the New York State Agricultural College, at Cornell University on January 12-15.

ON February 27, Professor Charles E. Lucke, head of the department of mechanical engineering of the Schools of Mines, Engineering and Chemistry, of Columbia Univer-

sity, will speak on the general subject of "Gas Power" before the Society of Arts of the Massachusetts Institute of Technology.

PROFESSOR HARRY GOVIER SEELEY, at one time professor of geology and geography in King's College, London, author of numerous contributions to zoology and paleontology, especially on fossil reptiles, has died at the age of seventy years.

By will of the late Professor Albert Gaudry, thrice president of the Société Géologique de France, that body receives a bequest of forty thousand francs, the income of which is to be applied in making suitable awards in recognition of meritorious work done in geology or paleontology, either by Frenchmen or foreigners. A portion of the fund may also be used in aiding deserving students in these branches.

THE late Professor Sacharjin has left two millions of roubles for the erection of a hospital in Moscow.

THE prize of the King of Belgium of the value of 25,000 francs will be awarded this year to the author of the best work on aerial navigation.

THE prize of five hundred dollars which is offered biennially by the Association of the Alumni of the College of Physicians and Surgeons, Columbia University, will be awarded in June, 1909. Essays in competition for the prize must be forwarded to Dr. H. E. Hale, 752 West End Avenue, New York, on or before the first of April.

It is announced that the recent fire at the Geological Survey building on F Street in Washington destroyed property to the value of about \$16,000. Ten thousand dollars' worth of surveying instruments were destroyed, and an expenditure of \$2,000 will be necessarily incurred for rewiring the building. The offices of the survey, like those of many other government bureaus in Washington that occupy rented buildings, are full of wooden partitions and other inflammable material, exposing valuable public property to the danger of destruction by fire at any time.

IN view of the scientific interests of the volcanic formation within the Rio Grande and

Cochetopa national forests in Colorado, President Roosevelt has made them a reservation under the act for the preservation of American antiquities. The district will be known as the Wheeler National Monument.

At the invitation of Mr. George Otis Smith an informal conference was held at the Cosmos Club, Washington, D. C., on January 2, 1909, for the purpose of discussing the progress of geologic work and with a view to bringing about a better coordination of the various investigations now being carried on. Professor T. C. Chamberlin presided at the meeting and of those invited to attend there were present: F. D. Adams, H. Foster Bain, Joseph Barrell, R. W. Brock, A. H. Brooks, Samuel Calvin, M. R. Campbell, T. C. Chamberlin, W. B. Clark, J. M. Clarke, Whitman Cross, H. P. Cushing, Arthur L. Day, B. K. Emerson, S. F. Emmons, N. M. Fenneman, H. E. Gregory, Arnold Hague, C. Willard Hayes, J. P. Idings, Arthur Keith, H. B. Kummel, A. C. Lane, Waldemar Lindgren, A. P. Low, W. C. Mendenhall, H. F. Osborn, T. W. Stanton, C. R. Van Hise, A. C. Veatch, David White, H. S. Williams, Bailey Willis.

THE Sheffield lectures at Yale University will be given this year, with two exceptions, by members of the scientific school faculty. The lectures will be illustrated and will be delivered on Friday evenings as follows:

January 15—"Growth of the North American Continent during Geologic Times," by Professor Charles Schuchert.

January 22—"The American Gem Stones," by Professor William E. Ford, '99 S.

January 29—"Paper Making from Wood," by Dr. Arthur L. Dean, '02 Ph.D.

February 5—"Dinosaurs: their Evolution and Distribution," by Professor Richard S. Lull.

February 12—"The Modern Steel Bridge," by Professor John C. Tracy, '90 S.

February 19—"The Safety Devices of the Human Body," by Professor Lafayette B. Mendel, '91.

February 26—"Influence of Geology on the History of Jamaica," by Dr. Rossiter W. Raymond.

March 5—"Recent Discoveries in Electricity and some of their Consequences," by Professor Lynde P. Wheeler, '94 S.

March 12—"The Iron Resources of the United States: their Past and Future," by Professor John D. Irving.

March 19—"Land Reclamation in the United States: the Problems, the Opportunity," by Dr. George T. Surface.

A STATEMENT regarding the anthracite industry of Pennsylvania has been prepared by Wm. W. Ruley, chief of the Bureau of Anthracite Coal Statistics, of Philadelphia. Mr. Ruley estimates that the shipments of anthracite for 1908 were 64,237,076 long tons, against 67,109,393 long tons in 1907, indicating a decrease of 2,872,317 long tons, or 4.28 per cent. If the quantity of coal sold to the local trade and used at the mines decreased in the same proportion, the total production in 1908 amounted to approximately 73,200,000 long tons, as against 76,432,421 long tons in 1907. Reports received by Edward W. Parker, statistician, of the United States Geological Survey, from state officials and others closely in touch with the coal-mining industry in the several states indicate that the output of the bituminous coal mines of the country in 1908 was between 320,000,000 and 330,000,000 short tons. If the final returns are found to agree closely with these preliminary figures they will indicate a decrease in production of 15 to 20 per cent. as compared with the production in 1907.

THE Third Congress on School Hygiene will be held in Paris from March 29 to April 2, 1909. There will be an exhibition in connection with the congress. The congress held its first meeting at Nuremberg in 1904, and its second in London in 1907.

UNIVERSITY AND EDUCATIONAL NEWS

GIFTS to the amount of \$346,466.05 were announced at the recent meeting of the trustees of Princeton University, of which the largest, \$200,000, was that of Messrs. David B. Jones and Thomas D. Jones, of Chicago, for the Palmer Physical Laboratory endowment fund. Other gifts were \$25,370 from the committee of fifty and \$34,377.07 from the General Education Board.

MORE than \$40,000 has been subscribed towards a fund of \$100,000 to endow a chair of physiology at the University of Cincinnati, in honor of the late Joseph Eichberg.

It is announced by President John Thomas, of Middlebury College, that \$91,685.50 has been contributed toward the \$100,000 needed to secure the D. K. Pearson building and endowment fund of \$100,000.

By the will of Dr. James G. Wheeler, Broughton, the James Millikin University, Decatur, will come into possession of his estate, estimated to be worth from \$75,000 to \$125,000.

THE Ohio State University has received a gift of \$10,000 from Mr. Robert T. Scott, Cadiz, the income to be used for the aid of poor students.

THE medical department of the University of Pennsylvania, has concluded arrangements for holding the first annual "Home Coming, or Progressive Medicine Week," to be given for the benefit of the alumni of the school, and to occupy the Easter vacation period. Plans are being considered to have each head of a department arrange, with the cooperation of his assistants, a program which will note deviations from the old standards, as well as lay stress upon principles which by constant practise have become crystallized. The alumni of the medical school who have distinguished themselves in their profession will be invited to cooperate.

ABBOTT LAWRENCE LOWELL, since 1900 professor of the science of government in Harvard University and previously since his graduation from Harvard College and the Law School a lawyer practising in Boston, will succeed Mr. Eliot as president of Harvard University.

DR. CHARLES H. HASKINS, professor of history in Harvard University, has been appointed dean of the Graduate School of Arts and Sciences, to succeed the late Professor John Henry Wright.

DISCUSSION AND CORRESPONDENCE

PECULIAR ELECTRICAL PHENOMENA

IN an article by Professor J. E. Church, Jr., in *SCIENCE*, November 6, 1908, page 651, entitled "Electric Disturbances and Perils on Mountain Tops," Professor Church describes

the peculiar brush discharges that emanated from the weather vane, the anemometer cups and other objects in an electric storm on Mount Rose, on October 20, 1907, between 6:30 and 7:30 P.M. He states also: "Whenever our hands arose in the air, every finger sent forth a vigorous flame."

It may be interesting to note that we find descriptions of similar phenomena in the Elizabethan era, and even in the days of Julius Cæsar. In the "Itinerary of Fynes Moryson" (Macmillan, 1908), Vol. 3, pp. 74-78, there is given an account of an electric storm on the night of December 23, 1601, at Kinsale, near Cork, Ireland. This storm, which took place in midwinter, and in a locality that was practically on the sea level, was preceded by "great lightning and terrible thunder" on the night of December 20, and by "continual flashes of lightning" on the night of December 21.

The following is Moryson's account:

All the night was cleare [i. e., brilliant!] with lightning (as in the former nights were great lightning with thunder) to the astonishment of many in respect of the season of the yeare. And I have heard by many horsemen of good credit, and namely by Captaine Pikeman, Cornet to the Lord Deputies troope, a Gentleman of good estimation in the Army, that this night our horsemen [who were] set to watch, to their seeming did see Lampes burne at the points of their staves or speares in the midst of these lightning flashes.

Again in North's "Plutarch," "Life of Julius Cæsar" as quoted in Porter and Clarke's edition of Julius Cæsar, p. 119:

Strabo the Philosopher writeth that divers men were seene going up and down in fire; and furthermore, that there was a slave of the soldiers that did cast a marvellous burning flame out of his hand; insomuch as they that saw it thought he had been burnt, but when the fire was out it was found he had no hurt.

Shakespeare has embodied this account of Plutarch's in his tragedy of Julius Cæsar, Act I., Scene 3, lines 15-25. See also Burritt's "Geography of the Heavens," revised edition, New York, 1859, p. 155, for a reference to a somewhat similar phenomenon as observed by Baccaria.

HENRY PEMBERTON, JR.

RAILROAD RATES FOR THE BALTIMORE MEETING

TO THE EDITOR OF SCIENCE: It has been the custom for many years past to obtain a railroad rate concession for the meeting of the American Association for the Advancement of Science and the affiliated societies. Formerly this was granted at one and one third—a rate, even at that time, far in excess of what could be obtained by a single professor who wished to conduct a handful of students on a geological excursion. To this rate was later added the twenty-five cents validation fee. Then came the concession of two cents per mile, for the Chicago meeting of 1907-8, a rate practically equivalent to the ordinary charges of the roads, to which must be added the validation fee. This year, the arrangements have been exceedingly liberal—one and three fifths plus the validation fee. Taking the rate from Philadelphia to Baltimore as an example: the one fare, \$2.40, and the three fifths, \$1.44, plus the validation fee, \$0.25, amount to \$4.09, a sum in excess of the regular round-trip fare of \$4.00.

I am aware that for those attending the meeting from a long distance, the rate granted *may* mean a slight reduction, but, even the scientific world is not made up of altruists, and members from the nearer localities will not pay more for their tickets than the ordinary round-trip fare, and trouble themselves besides to obtain certificates, deposit them for validation, call for them, and re-sign for the return trip—four unnecessary wastings of time—for the sake of accommodating those from a longer distance, and there is thus a possibility that the certificates presented may fall short of the required number, with the result of adding greatly to the expenses of members from a distance who put faith in the certificate plan.

I do not know, nor care to know, who is responsible for this most remarkable rate, but I do know what has been done by private individuals, and I am convinced that, with an organization so numerically strong as the American Association for the Advancement of Science and the affiliated societies at its back, the committee, if it be indued with a real desire and determination to obtain con-

cessions that are worth while, will never again offer to the most powerful scientific body of the United States, an illusory grant.

H. NEWELL WARDLE

QUOTATIONS

HARVARD'S NEW PRESIDENT

It would appear that all the recognized demands, exacting though they are, have met satisfactory compliance in to-day's selection of a president of Harvard. Professor Lowell's attainments as a scholar, although well known for many years to the inner circle, have recently received new recognition, both in America and abroad. It is quite beyond question that his recent notable volumes on "The Government of England" have placed him first among contemporary American scholars in the field of political science. To his skill as an administrator the success of the Lowell Institute affords striking testimony, while his deep and active interest in educational questions has received proof in his effective service as a trustee of the Institute of Technology and as a member, for nine years past, of the Harvard faculty. He is a Bostonian by inheritance, by nativity, and by tradition. He is a Harvard man by education, both collegiate and professional; the university can claim no stancher allegiance than his has been. At fifty-two nature has permitted him to retain a nimbleness of mind and body which in the case of most men takes its departure at a much earlier age. Indeed, from every point of view his selection seems obvious, logical and fortunate.

The hand of the president is potent at Harvard; more so perhaps than in any sister institution. Harvard government is that of a limited monarchy, but with the right type of monarch the administration can be made to veer pretty close to the status of a benevolent despotism. To say that it has veered in this direction during the last two or three decades is the highest tribute one may pay to the consummate skill and personal power of President Eliot. But this very development, this centralization of power, influence and responsibility which the retiring Nestor among

college presidents has brought into being will serve to make his mantle fall heavily upon him who must now take it up. To bear it as it has been borne will prove no easy task.—*Boston Evening Transcript*.

SCIENTIFIC BOOKS

ELIOT AND THE AMERICAN UNIVERSITY¹

Forty years ago, there was chosen to the presidency of Harvard College, a young professor of chemistry, who had none of the qualities then commonly supposed to be necessary in the position which he held. He was not a clergyman, not a teacher of philosophy, not venerable and not spiritual, merely young, industrious, clear-sighted, scholarly and fearless. Harvard College was in those days only a small institution, chiefly for boys, "a respectable high school where they taught the dregs of learning," as its most popular teacher then described it. Still it was the best we had and our own "our oldest, richest and freest university," even as it is to-day.

In 1868, the young president found an institution of the old type, with some most charming and gifted professors, and others dry as dust. Its work was all elementary in character, the subjects taught were held to be of unequal value, the Greek and the Latin standing in official precedence. Of advanced study there was little, and that little existed in the unique personality of Louis Agassiz and of Asa Gray. It was essentially a boys' school, and a school of the type which forces set tasks on unwilling youth. One of the graduating class of 1878 said to the present writer, at the time that in his class there were but two men (J. W. Fewkes was the other) "who had any interest in natural history or in anything else." Doubtless this was an exaggerated statement, but it represented fairly the attitude of the college boy in those days of prescribed courses and text-book recitations in elementary subjects. In those days, too, the professional schools had no foundation in science or in culture, and the instruction given in them was guiltless of pedagogic methods or

¹"University Administration," by Charles W. Eliot, Boston, Houghton, Mifflin Co.

ideals. In almost all departments of Harvard College advanced education was a grind rewarded by a degree. The degree was a badge of social and intellectual achievement, not a disclosure of the secret of power.

To change all this was not an easy task, and the young president had grown middle-aged before the greater part of his work was achieved. He rightly interpreted his position as representing in no sense a fact accomplished. It was of necessity a continuous struggle; a struggle for greater means, for better men and for higher ideals. An American university is never finished.

Fortunately for himself and for the nation, Dr. Eliot has lived to wear out all opposition; he has seen Harvard College made over after his own fashion, and he has seen it lead the race in a long procession of institutions, one and all endeavoring to follow in its trail. The various impulses of originality in other institutions, notably those originating with Andrew D. White, at Cornell, and with Daniel C. Gilman, at Johns Hopkins, have been absorbed by Harvard, and in general carried to the greatest success yet possible under American conditions. To Cornell we owe originally the doctrine of the democracy of studies, the idea that no one shall say which subject or which discipline is best until we know the man on whom it is to be tried. To Johns Hopkins we owe the idea that advanced work in any subject has a greater culture value than elementary work in the same or other subjects. Both these doctrines have found their place in the elective system at Harvard.

In the lectures on university administration at Northwestern University, President Eliot explains in detail, in simple undramatic fashion, the plan of his work at Harvard, its methods and its results. That the most successful of college administrators should regard the methods which he has himself used as typical and desirable, is natural enough. If other methods had seemed better, he was perfectly free to use them. This volume is therefore an exposition of what Harvard actually is, and the reasons why it is so, in so far as these depend on administrative methods of

any sort. The book is the best of reading for college men, and to the college president it is a veritable hand-book full of suggestiveness on every page.

The board of university trustees at Harvard numbers seven, with the president of the university as the executive head. This number is most favorable to the management of business, and this relation the one most likely to insure devotion and continuity in executive affairs. The disadvantages of large boards, of honorary, ex-officio and absentee trustees, clearly appear in the light of Harvard's experience with a better way. The importance of beginning with young men appears here as elsewhere, and with this Dr. Eliot has the significant remark, "Strangers will, as a rule, not make so good trustees as the children of the house."

In the suggestions as to professors' salaries, Dr. Eliot is rather conservative, especially as regards the younger men, although the professor is better paid at Harvard at present than in any other American college or university. The instructor, he thinks, should begin on the amount a young unmarried man can manage to live on. After a few years of annual appointment, a permanent position with a small increment should be given, and still later, as assistant professor, he should receive a sum on which he may marry but without luxury or costly pleasures. At forty, if growth goes on, the teacher may hope for a professorship, and a full salary at fifty or fifty-five. One difficulty in all this comes from the fact that growth is largely conditional on travel, and travel is a "costly pleasure." To starve a man until he is forty is not to provide for a productive career for the fifteen years that follow.

In all financial matters, President Eliot has been preeminently practical, and the paragraphs relating to the business affairs of the college are thoroughly wise and pertinent. The exclusion of the college president from initial responsibility in these matters is a mistake, and one which has been adopted in too many of our institutions.

The coordination of the influence of the alumni, as represented by the board of over-

seers at Harvard, is a matter on which Dr. Eliot justly lays especial emphasis.

In the development of the faculty at Harvard, stress has been laid on the individual teacher rather than on the department. As a result of this the department or group executive appears rather as a servant or representative, than as a director or manager of his colleagues. The president stands in the same relation to all the various groups. The system, in vogue in many institutions, by which the professors are brought together into groups under the headship of some dean, who rules over them, the dean in turn ruled over by the president, has never taken root at Harvard. Deans, or sub-executives, are doubtless necessary in large institutions, but they should not be created until they are needed. Above all, what is needed by the executive in all branches is not so much authority to execute as the power and the duty to initiate. Nowhere is the necessity for the concentration of initiative so important as in the duty of the nomination of professors. President Eliot shows clearly the reasons why formal faculty initiative fails in this regard. But there are good reasons why formal faculty acceptance of such nominations is also most desirable. No professor should be added to the faculty against the sober judgment of those who may be his colleagues.

President Eliot devotes one optimistic chapter to the consideration of the greatest of his educational innovations, the elective system. This system has everywhere and of necessity replaced the classical system, which considered but two or three of the many phases of scholarship and life. For Greek-minded men, to use Emerson's phrase (and a very noble type of men they are) the classical training gave a basis of scholarship on which later studies could build to advantage. But the great body of our youth of promise are anything but Greek-minded, and the old classical course opened to them no door worth their entering. The elective system opens many doors and admits many types of men. No two men need exactly the same sort of training for their own best development. The student is a better judge of his own needs than

any group of educational philosophers who have never known him. Here, as elsewhere, the student learns from his own mistakes. Moreover, the elective system brings the student in contact with the best teachers he knows, and the teacher in turn is refined and stimulated by the students who have chosen his work. To the patchwork courses which followed the break-up of the classical system, the elective courses are in every way to be preferred. The mind is made strong by the continuous study of something, and in prescribed courses made up of odds and ends unrelated to any central purpose, thoroughness in any line is impossible. At the present time there is a distinct reaction against the elective system, but not in favor of any other system which has been actually under trial. The elective system will not make scholars out of rich and idle lads whose only interests in college are in games and social pleasures. Once in a while such a one is reclaimed, but the percentage is too small to justify the effort. The elective system is as good as any other system for such as these, but no system will make a man out of a boy who has himself no interest in the process. It is the duty of the college to withhold its degrees from idlers of whatever class. To give the titles of higher education where the substance is lacking is to cheapen our own work. The remedy for slipshod college work is found in the scholarship committee, rather than in the arrangement of courses of study. The final answer to criticisms of the elective system is to recognize its occasional abuses by professors as well as by students, and to ask, what else will you put in its place?

Doubtless a prescribed course is sometimes effective, as in engineering or in medicine, but only where it is prescribed by the nature of the subject. Mathematical subjects are linked together, one dependent on another, and the student desiring mathematics makes no complaint of this prescribed order. But for courses of mixed science, literature, art and philosophy, so many units of one, so many of another, disjointed fragments brought together in the name of culture, the student can have

no respect. Required courses of this fashion have passed away never to return. The checks on the elective system must come from the student himself. He must be trained to guard himself from premature specialization on the one hand and from limp diffuseness on the other. If he is a real student, the safe mean leans strongly toward the side of specialization, for after all this is but another name for thoroughness. "The mind is made strong by the thorough possession of something."

The writer once heard President Eliot disclaim any unusual degree of prophetic vision, allowing for himself only an honest industry, attacking one problem as it arose after another, with such solution of each as might be within the range of practical action.

One of Dr. Eliot's predecessors in Harvard was once complimented on the logical coherence of his sermons. He disclaimed all special excellence in this regard. "I write one sentence," he said, "then I thank God and write another." President Eliot has himself accepted this definition of his method. One thing done, he turns to and does the next, and this is the essence of his educational foresight. He does the next and the next, never stopping with the first result or the first achievement; and thus he has made of the administration of Harvard a continuous struggle, while all our other colleges have followed near or far along the same lines of progress.

And to the young man on whom his mantle shall fall, the administration of Harvard will still be a struggle. Nothing is completed, nothing is settled, nothing is final. New lines of development will follow swiftly on the old. The university must be separated from the college, and must be devoted wholly to the work of men as distinguished from the work of boys. All trace of the trade school must be eliminated from the training of professional men. The university professor on the firing line of scientific advance must be maintained and appreciated and none the less the college teacher whose first aim shall be to develop the boy into the sound, sober and enlightened man. The unification of higher education has been in a degree accomplished.

The substantial requirements for entrance, the broad outlook of the elective system, the intensive thoroughness of the graduate professional school, the glorification of the spirit of research, all these are exemplified in the Harvard of to-day. The Harvard of to-morrow will lead in the differentiation of the work of men, the separation of boys and boys' teachers from men and men's teachers. It will not be Harvard College as it was, nor interchangeably Harvard College and Harvard University as it is to-day. It will be a university resting on a college foundation, a university worthy of the eighty millions of free men who form its constituency, a university fit to frame the highest aspirations of the noblest youth of the republic.

DAVID STARR JORDAN

SCIENTIFIC JOURNALS AND ARTICLES

It is ever a wonder to us in America that German biologists can so easily start and maintain a new periodical. No sooner does a science become well defined and gain a number of workers than the proper periodical is forthcoming. These remarks are called forth by the appearance of the *Internationale Revue der gesamten Hydrobiologie und Hydrographie* (Leipzig: Klinkhardt), of which the first (double) number appeared in May. The backing of the magazine is indicated by the names on the cover. R. Woltereck (of Leipzig and Lunz) is the editor. B. Helland-Hansen (Berlin), G. Karsten (Bonn), A. Penck (Berlin), C. Wesenberg-Lund (Hilleröd), R. and F. Zachokke (Basel) are the other members of the editorial staff. The Prince of Monaco, Agassiz, Chun, Forel, V. Hensen, R. Hertwig, Murray, Nansen, O. Pettersson and Weismann have lent their names to the undertaking. The first number contains 307 octavo pages, of which the first half contain original contributions; those of Weismann, Murray, R. Hertwig and Issel being essays written especially for the introduction of the new journal. A paper by Nathansohn begins a projected series on the biology of the plankton; one by A. Fischel deals with very successful intravital staining

of *Cladocera*; one by Klausener treats of the annual cycle of the fauna of alpine lakes; and one by Götziner in the first part of a monograph on Mitter Lake at Lunz, in the Austrian Alps. The remainder of the number contains abstracts of reports, summaries of results, critical reviews, notices from stations and a list of recent literature. There are eight plates and numerous text-figures. Certainly the periodical starts out with the highest ideals and it will be a great stimulus to hydrobiology. It deserves, as it will receive, the most active support of the numerous American workers in this field. C. B. D.

The Independent begins with its issue for January 7, 1909, a series of articles on the fourteen universities of this country, written by Dr. Edwin E. Slosson, of the editorial staff and previously professor of chemistry in the University of Wyoming. Harvard is the first institution discussed and the others to follow in the order named at intervals of one month are: Yale, Princeton, Pennsylvania, Chicago, Johns Hopkins, Stanford, California, Michigan, Wisconsin, Minnesota, Illinois, Cornell and Columbia.

BOTANICAL NOTES

TREES AND FORESTRY

THE University of California has done well in publishing Mr. N. D. Ingham's bulletin (No. 196) on "Eucalyptus in California." In 88 pages the author by means of plain descriptions and 70 excellent half-tones gives his readers some very clear and usually very new ideas as to these wonderfully interesting trees as they grow in California.

Major George P. Ahern's "Annual Report of the Director of Forestry of the Philippine Islands," for the year ending June 30, 1907, is of interest to forestry students in this country as showing the considerably different problems which pertain to work in the islands. Two maps help to give a clearer idea as to the available forest tracts in Negros Occidental and Mindoro.

Two years ago Rolland Gardner, of the timber-testing laboratory at Manila, published a bulletin (No. 4) on the "Mechanical

Tests, Properties and Uses" of thirty-four Philippine woods, and a year later, the edition being exhausted, a second, revised edition was brought out. In its present form it includes a popular discussion of the qualities of woods and the meaning of timber tests, methods of testing and results of tests, structural qualities, appearance and uses. In the last-named section, in addition to common names the scientific names as far as they can be determined are given. An interesting comparison of the tests of Philippine and American woods shows that the former rank very high.

L. A. Dode's "Notes Dendrologiques" in the *Bulletin de la Société Dendrologique de France* (1907) includes notes on *Ailantus*, *Catalpa*, *Sorbus*, *Clerodendron* and *Platanus*, in most of which genera the author of course finds "new species"!

ANOTHER BOOK ON NORTH AMERICAN TREES

GEORGE B. SUDWORTH, dendrologist in the Forest Service, has made an important contribution to our knowledge of the trees of the western part of North America by the publication (October 1, 1908) of a thick pamphlet of 441 pages under the title "Forest Trees of the Pacific Slope." It is the first part of a work intended to deal with all the native forest trees of North America north of the Mexican boundary. This volume contains an account of the trees known to occur in Alaska, British Columbia, Washington, Oregon and California. Part II. will be devoted to the Rocky Mountain trees, part III. to the trees of the southern states, and part IV. to the trees of the northern states. The work when completed will therefore be one of the most important of those yet published by the Forest Service, and must prove of great value to students of forestry and especially of dendrology, while as a matter of course it will be indispensable to the systematic botanist. It may be asked why should the United States Forest Service incur the labor and expense of publishing a comprehensive work on the North American forest trees when we already have Sargent's "Silva" in fourteen great quarto volumes; Sargent's "Manual of the Forest

Trees of North America"; and Britton's "North American Trees," but it does not require a long perusal of the book before us to convince one that it contains much that is not to be found in other books, and that it can easily justify its existence.

In the first place it is written from the dendrologist's point of view. It is rather a forester's book than one for the botanist, and so contains some things that are not to be found in other books on trees. Thus one finds under each species a paragraph relating to the longevity of the trees, another as to their particular habitat, still another in regard to the climatic conditions under which they grow, one on tolerance (of especial value to the practical forester) and one on their reproduction (also of very high value to the forester). The descriptions are non-technical and are accompanied by good life-size figures of characteristic parts, as leaves, cones, fruits, seeds and less commonly the flowers. In only a few instances was it necessary to reduce the figures below their natural size.

In the second place it is desirable that there shall be some authoritative *silva* for the use of the men who go into the United States Forest Service. In this book care has been taken in regard to the selection of English names for the species, and in like manner where there has been a question as to the proper scientific name one is here designated for use by the official dendrologist. In regard to this latter point it seems to the writer of this notice that on the whole a conservative course has been taken. While many trees appear here under unfamiliar names, there seems to be a good reason for every change made. There is an entire absence also of the species-making mania, and the reader soon gets the impression that the author is more interested in giving such a clear idea of the species that they may be recognized in the forests than in making out that certain observed variations are the sure indications of new species.

The definition of a tree followed by the author includes "woody plants having one well-defined stem and a more or less definitely formed crown, and attaining somewhere in

their natural or planted range a height of at least eight feet, and in diameter of not less than two inches." This definition is not, however, allowed to exclude unbranched cactuses, yuccas and palms. The uniform recapitalization of all specific names is greatly to be commended, as also the clear type (of two sizes) and the exact illustrations. Two good maps of the region covered and a good index complete this altogether admirable publication.

FUNGUS NOTES

In a recent number of *Rhodora* (January, 1908) Dr. W. J. Farlow begins the publication of "Notes on Fungi," which promise to yield critical discussions of much value. He shows that what has been known as *Corticium tremellinum* var. *reticulatum* is in the first place not a *Corticium*, but a *Tremella*, and that the variety is a distinct species, to be known hereafter as *Tremella reticulata*. He shows that what has been known as *Synchytrium plurianulatum* (a parasite in species of *Sanicula*) is in reality *Urophlyctis pluriannulatus*, and that a uredineous parasite of *Rubus neglectus* and *R. strigosus*, hitherto known as, or confused with, *Phragmidium gracile* is *Pucciniastrum arcticum* var. *americanum*. He is further of the opinion that the *Pucciniastrum* on *Potentilla bidentata* is *P. potentillae*. Further notes from this source will be eagerly looked for by mycologists.

In *Annales Mycologici* (V., No. 7, 1907) Professor F. L. Stevens figures and describes "Some Remarkable Nuclear Structures in *Synchytrium*." The paper is a record of facts, and the author does not attempt to base any conclusions upon what he has yet seen. Other recent fungus papers by the same author are "An Apple Rot due to *Volutella*" and a "List of New York Fungi" in the March and May numbers of the *Journal of Mycology* (1907), and "The Chrysanthemum Ray Blight" in the *Botanical Gazette* (October, 1907). The fungus which causes the ray blight on the chrysanthemum appears to be new and is described as *Ascochyta chrysanthemi*.

Heinrich Hasselbring's paper on "The

Carbon Assimilation of *Penicillium*" in the *Botanical Gazette* for March, 1908, is a contribution to our knowledge of the chemistry of the assimilation of some of the simpler compounds by plants. Among the results noted is the fact that "alcohol, acetic acid and the substances from which the acetic acid radicle CH_3COO — is easily derived are assimilated by *Penicillium glaucum*."

Mention should be made here of Scott and Rorer's paper "Apple Leaf-spot caused by *Sphaeropsis malorum*" in Bulletin 121 of the Bureau of Plant Industry of the U. S. Department of Agriculture; of W. H. Lawrence's record of "Some Imported Plant Diseases of Washington," in Bulletin 83 of the Oregon Experiment Station, and Cook and Horne's "Insects and Diseases of the Orange," in Bulletin 9 of Estacion Central Agronomica de Cuba.

Here also may be mentioned Professor Harshberger's paper "A Grass-killing Slime Mould" in the *Proceedings of the American Philosophical Society*, Vol. XLV., recording a case in which the plasmodia of *Physarum cinereum* killed the blades of grass over which they had grown.

CHARLES E. BESSEY

THE UNIVERSITY OF NEBRASKA

SPECIAL ARTICLES

SOME REMARKS ON THE CULTURE OF EASTERN NEAR-ARCTIC INDIANS

DURING the past summer, 1908, the writer undertook an ethnological expedition into the James Bay region of Canada, for the Department of Anthropology of the American Museum of Natural History of New York. The original intention was to journey to Moose Factory and thence to the eastern coast of the bay, touching at Rupert's House, Eastmain River and, perhaps, Fort George, at which posts it was supposed access might possibly be had to the Naskapi Indians of Labrador, who, it was thought, might come down to these points during the summer, for the purpose of trade. On arriving at Moose Factory, it was learned that the Naskapi could not be reached via the west coast of Labrador, usually known

as Eastmain, and that they did not come out to any of the posts along that shore. At Nitchequon, a post situated in the Labrador interior, fifty-five days' journey from Rupert's House by canoe, and still in the hunting territory of the Northern Cree, the Naskapi are known to come in winter when driven by starvation. Otherwise they are confined to the interior of Labrador proper, held back on the east and north by the Esquimaux, on the west by the Northern Cree, and on the south by the Montagnais.

As conditions were not favorable for study of the Naskapi, our attention was turned to the ethnology of the Northern Cree. The Northern, or perhaps more properly the Eastern, Cree range from Nitchequon on the north, south to the height of land around James Bay, west to the Albany River and Agonska Island. There are no Cree between this post and York, because the Northern Ojibway have worked northward to the coast and thus have separated the York Cree from the rest. So far as could be learned from the Hudson's Bay men and Indians, this has taken place within comparatively recent times, and it was also stated that the Western Cree came originally from the vicinity around James Bay, being induced to go westward by the Hudson's Bay Company. Both the York Cree and the Western Cree seem to be considered by the Eastern Cree to be somewhat different from the Eastern Cree, although admittedly the same people. Several dialects of their language are recognized by the eastern band, but the changes appear to be perfectly regular and phonetic, not affecting the grammar in any way.

The Eastern Cree claim to have always lived in the region that they now inhabit, and recognize several bands or subdivisions, known according to the locality which they inhabit. The Crees know themselves generally as *Muskéko-wug*, or "Swamp People." The social unit is the patriarchal family and there seems never to have been any clan organization among them. Village life is, and apparently was, unknown; for economic conditions caused single families to live by themselves, far apart from any others, and rendezvous was

made every spring at some spot previously decided upon for the purpose of reuniting. At this time, the feasts, councils and meager ceremonies of these people were held. Nowadays, the hunters come to the Hudson's Bay posts every spring to trade their furs for supplies for the next year, and this coming together takes the place of the old spring meeting. Chiefs were never elected or chosen, but acquired their office through prestige by tacit consent on the death of the former incumbent. As the people rarely came together, excepting at the spring meetings, or in case of war, the chief's influence was small in comparison with that of the shaman. Shamanism, or "conjuring," as it is called in the north, is still quite extensively carried on for warlike expeditions, hunting, love-making and other purposes. Conjuring houses are still built and used. A shamanistic society, very loose in form, but apparently corresponding to the Midewin of the Ojibway, occurs. There are but two degrees, and admission to these is through dreams. There are no initiatory ceremonies. So far as could be learned, members of this society do not attempt to cure disease. Apparently this is done by herb doctors.

The material culture of these people is now considerably debased through constant contact with the Hudson's Bay Company. Clothing in the old days was made of caribou skin, tanned without the hair in summer; in winter, of caribou skin with the hair, or of beaver and other furs. Garments were often made of twisted and woven rabbit skins. Coats with sleeves, hoods and mittens were worn by both sexes. The habitations consisted of conical or dome-shaped lodges, covered with painted skins, bark or brush. No mats were used for this or any other purpose, as articles of woven rabbit-skin seem the only fabrics made. Owing to climatic conditions, agriculture was unknown, a few berries furnishing the only vegetable food. Hunting, and, secondarily, fishing were the great resources of life. As hunting has not been checked, but rather given an impetus, by the advent of the Hudson's Bay Company, all the ancient superstitions regarding animal life may still be found in full force. Most interesting of these are a series

of observances regarding the killing of the bear. While all the eastern Algonkins have observances of this order, they seem to have become much more elaborated among the Eastern Cree.

Pottery was unknown, steatite taking its place. Semilunar knives, here used as scrapers, other knives and some arrow points were rubbed out from slate. In some parts, at least, arrow points seem to have been chipped; and in others, made of bone and antler. The grooved axe was used. Basketry, except simple vessels of birch or pine bark, was unknown. Birch bark canoes were used.

Syllabics, invented by missionaries, are now used for communication in their own language, though the Cree still employ mnemonic devices of their own invention for the same purpose. Information was obtained which seemed to show that in olden times pictorial writings on birch bark, similar to those found among the Ojibways, were known. The primitive form of art seems to have been painting, and the lines employed were geometric.

Little folk-lore was collected, and this was, in the main, typically Algonkin, but some apparently resembles the Esquimaux.

A comparison of the writer's notes with Lucien M. Turner's account of "The Nenenot or 'Naskopie' " Indians,¹ and conference with Indians and white men who had been in the Naskapi country, seems to show that the culture of these people is identical with that of the old Cree. Considering the absence of agriculture, the lack of village life and clan systems, the loose social and political organization, the absence of pottery and the ordinary forms of fabrics, and the comparative difference of artifacts in general, as here noted—it may perhaps be well no longer to consider the region inhabited by the Eastern Cree and the Naskapi as belonging to the Eastern Woodland culture area, a region characterized throughout by its agricultural and village life, its comparatively highly developed social and political organization, its pottery, clothing

¹ Lucien M. Turner, "Ethnology of the Ungava District," Eleventh Annual Report, Bureau of Ethnology, 1889-90, pp. 167-350.

made from skins tanned without the hair, fabrics, woven basketry, and the like. Dr. Frank G. Speck, of the Department of Archeology of the University of Pennsylvania, who spent last summer among the Montagnais of Lake St. Johns, arrived independently at the same conclusion in studying these people. It is the suggestion of the writer, then, that the culture of the region of Subarctic Eastern America inhabited by the Cree, Naskapi, and Montagnais, might better be known hereafter as the Eastern Subarctic, or Labradorian, cultural area, as it is apparently so different from the eastern woodland area with which it has hitherto been classed.

ALANSON SKINNER

AMERICAN MUSEUM OF NATURAL HISTORY

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
SECTION A—MATHEMATICS AND
ASTRONOMY

COMPARATIVELY few papers on pure mathematics appeared on the program of Section A in view of the fact that the American Mathematical Society held its annual meeting in affiliation with the association. The address of the retiring vice-president, President E. O. Lovett, the Rice Institute, Houston, Texas, was read by the secretary of the section. It was entitled "The Problem of Several Bodies, Recent Progress in its Solution," and an abstract of it has appeared in a recent number of SCIENCE.

The following members of the section were elected as fellows of the association: David R. Allen, Joseph Allen, R. B. Allen, Harriet W. Bigelow, Oskar Bolza, W. H. Bussey, B. E. Carter, E. F. Chandler, Abraham Cohen, E. H. Comstock, H. A. Converse, S. A. Corey, J. A. Cragwall, F. F. Decker, C. C. Engberg, F. C. Ferry, F. E. Fowle, Philip Fox, William Gillespie, C. C. Gore, C. O. Gunther, U. S. Hanna, A. E. Haynes, Alfred Hume, W. J. Hussey, Kurt Laves, A. H. McDougall, Max Mason, Frank E. Miller, J. S. Miller, W. F. Osgood, J. M. Page, M. T. Peed, James Pierpont, S. C. Reese, W. J. Rusk, P. L. Saurel, G. T. Sellew, E. B. Skinner, A. G. Smith, D. E. Smith, P. F. Smith, Joel Stebbins, R. P. Stephens, L. B. Stewart, H. D. Thompson, E. B. Van Vleck, Oswald Veblen, H. S. White, F. S. Woods.

The sectional committee of Section A nominated the following members of the association,

who had not affiliated with any particular section, for fellowship in the association: Eugene Davenport, dean of the College of Agriculture, University of Illinois; E. K. Putnam, acting director of the Davenport Academy of Sciences; J. E. Stubbs, president of the State University of Nevada. These were also elected as fellows by the council.

In addition to the address of the vice-president, the following sixteen papers were read before the section:

1. V. M. Slipher: "The Spectrum of Mars."
2. E. B. Frost and J. A. Parkhurst: "Spectrum of Comet Morehouse."
3. E. E. Barnard: "On the Changes in the Tail of Comet Morehouse."
4. Frank Schlesinger: "The Orbit of the Algol-type Variable Delta Libræ."
5. Milton Updegraff: "The 6-inch Transit Circle of the U. S. Naval Observatory."
6. F. R. Moulton: "On Certain Implications of Possible Changes in the Form and Dimensions of the Sun, and Some Suggestions for Explaining Certain Phenomena of Variable Stars."
7. R. H. Baker: "On the Spectra of Alpha Virginis and Similar Stars."
8. F. C. Jordan: "The Orbit of Alpha Coronæ Borealis."
9. E. B. Frost: "Radial Velocities in Professor Boss's Star Stream in Taurus."
10. Philip Fox and Georgio Abetti: "The Interaction of Sun-spots."
11. Harris Hancock: "Elliptic Realms of Rationality."
12. Artemas Martin: "Algebraic Solution of the 'Three Point' Problem."
13. J. B. Webb: "Esperanto and a Sexdecimal Notation."
14. J. A. Miller and W. R. Marriott: "Comet Morehouse."
15. L. A. Bauer: "On the Interpolation Formula of Geophysics."
16. H. W. Fisk: "A Graphical Aid to the Determination of Latitude and Azimuth from Polarix Observations."

In the absence of their respective authors the paper by V. M. Slipher was read by J. A. Miller; the joint paper by E. B. Frost and J. A. Parkhurst was presented by W. S. Eichelberger; the three papers by Frank Schlesinger, R. H. Baker and F. C. Jordan, respectively, were read by J. A. Brashear; F. R. Moulton's paper was read by E. D. Roe; G. F. Hull presented the two papers by E. B. Frost and by Philip Fox and Georgio Abetti, respectively; the papers by E. E. Barnard and Artemas Martin, respectively, were read by

title. The remaining papers were read by their respective authors and the abstracts which follow bear numbers corresponding to those of the titles in the list.

1. The paper by Mr. Slipher gives the results of a photographic investigation of the extreme red end of the spectrum of Mars made with special reference to water-vapor in the planet's atmosphere. It is a part of an extensive and detailed presentation which is to appear in the *Astrophysical Journal*.

2. The comet was observed photographically with a prismatic camera or with a quartz spectrograph on fifteen nights. The third and fourth carbon bands were identified, and the first, third and fourth bands of cyanogen. The plates taken with the objective prism over the six-inch Zeiss doublet show well the separate spectral images of the tail, running off the plate in most cases at a distance of over 3° . Wave-lengths were given off from unidentified bands. A brief account of the observations by E. B. Frost and J. A. Parkhurst appeared in *SCIENCE*, January 2, 1900.

3. Professor Barnard's paper deals with the remarkable changes in the appearance of the comet and of its tail as shown by the photographs of it, and an attempt to explain the phenomena.

There were a number of outbreaks in the comet in which volumes of matter were thrown off which could be traced for several days, on the photographs, as they receded from the comet. On one occasion the tail was violently curved and switched forward in the direction of its lateral motion. At another time the masses not only receded from the comet, but their lateral motion was also accelerated and became greater than that of the comet in the same direction. This acceleration was apparently in defiance of the laws of gravitation.

It is suggested as an explanation of these anomalous phenomena that disturbances of some kind occur in the interplanetary spaces, perhaps temporary in their nature and location, which may accelerate or retard, and bend or break the tail of a comet when they are encountered by it. It is suggested, also, that these regions of disturbance may be due to the same or a similar cause as that which produces magnetic disturbances on the earth—that is, that they are due to forces which are encountered by the comet and which have their origin in disturbances on the sun. An encounter of this kind might account for the sudden brightening of some comets, such as that of Sawerthal's in May, 1888. It might also cause the disruption of large volumes of the

cometary matter such as are shown in the photographs of Morehouse's comet on October 15, etc.

4. Sixty spectrograms of this Algol-type variable were obtained at the Allegheny Observatory during this year. These indicate a nearly circular orbit with a range of 146 kilometers per second. The center of gravity of the system is approaching us at the high rate of 46 kilometers per second. The light curves of this variable has been the subject of a recent exhaustive investigation by Kron. A study of the results obtained by him, and of the spectrographic data, enables us to infer the following with regard to the constitution of the system, upon the assumption that the light changes are caused by an eclipse. The two stars in the system have nearly equal diameters (about two and a half that of the sun), but one of them is nine times as bright as the other. Their average separation is about one thirtieth of that between the earth and the sun. If we assume that the two stars are equally dense the mass of each would be about six tenths and the density about one twenty-fifth that of the sun.

In discussing a series of measurements made two years ago upon β Persei, Professor Schlesinger showed that in the case of this star there is a discrepancy between the phase demanded respectively by the light and velocity changes. Further investigation has confirmed the reality of this discrepancy and has shown that it can not be accounted for by any uncertainties in either the photometric or spectrographic data. It is interesting to notice that the same discrepancy is present in the orbit of δ Libræ. In this case the light phase lags more than two hours behind the velocity phase. The discrepancy is, therefore, somewhat greater than in the case of β Persei, but it is in the same direction.

5. Professor Updegraff gave the following account of the six-inch transit circle of the U. S. Naval Observatory:

This instrument was acquired by the Naval Observatory with a view to its employment in doing fundamental work. The nine-inch brass transit circle made by Pistor and Martine, of Berlin, and mounted in the old Naval Observatory in 1805 was considered unsuitable for fundamental work of the highest class, and after the removal of the observatory to the new site on Georgetown Heights about the year 1893, the new six-inch steel transit circle was designed by Professor Wm. Harkness and was built by the well-known instrument makers, Warner & Swasey, of Cleveland, Ohio. The instrument was mounted in the west transit circle house at the new Naval Observatory

in December, 1897, and was first brought into use in June, 1899. A description of the six-inch transit circle may be found in volume III., Part 4, of the *Publications* of the Naval Observatory, together with an account of the work done with it up to March, 1901.

The design of the instrument is substantially the same as that of the later Repsold meridian circles, and certain features have been the subject of considerable controversy. It was, I think, the first large instrument of this kind to be built of steel, which being a much stiffer metal than brass is expected to diminish errors due to flexures. This feature has been much criticized, but the example set by Professor Harkness has been followed by the Repsolds in making the new transit circle for the observatory at Kiel, Germany, which is also of steel, and the prospect is that steel or some other rigid metal will finally be recognized as preferable to brass for the construction of large instruments of this kind.

When brought into use the new instrument was found to have various defects, the most important of which, an extraordinary variability in azimuth, was found to be intimately connected with temperature. After a very troublesome investigation this was found to be due to two causes. The cast-steel bed plates which supported the instrument were, through non-homogeneity of the metal, distorted by temperature changes, and the marble piers of the instrument were not properly supported on their foundations. New bed plates of cast iron were provided, and the marble piers of the instrument were replaced by brick piers. These measures gave relief, and rendered the instrument remarkably stable in azimuth.

A peculiar but not serious difficulty has arisen from the construction of the tube of the telescope of steel. In a brass telescope of moderate size the changes in focal length of the object glass with temperature is nearly the same as the expansion and contraction of the tube with changes of temperature. But the coefficient of expansion of steel is smaller than that of brass, and in the case of the tube of the six-inch transit circle is not sufficient to make up for the change of focus of the object-glass. This makes necessary a change of stellar focus from winter to summer and vice versa.

In the fall of 1901 the instrument had been put in good condition, and for about one year following was employed in observations of the fixed stars and also in observations of the sun, moon and planets. The latter work with the instrument was continued up to September, 1903, when work

was discontinued, and practically no observations have been made with it since that time. In 1906 a transit micrometer made by Warner & Swasey was substituted for the old eye-end and a few practise observations were made by various observers.

The plan for the future work of the instrument is given in a general way in the report of the superintendent of the U. S. Naval Observatory for the fiscal year ending June 30, 1908, which has just been issued. This plan involves an attempt to render the observations of the sun and fixed stars and, consequently, of all bodies which are referred to them, of as strictly fundamental a character as is practicable.

The importance of such work to the science of astronomy and in the plan of work of an observatory maintained by the government is generally recognized by astronomers. It is expensive and laborious and in some respects perhaps less attractive than some other kinds of astronomical work in that it can not excite the interest or occupy the attention of the general public to any great extent. But for its proper performance, technical qualifications of a high order are required. Partly for these reasons, no doubt, this work has, with a few notable exceptions, not been as efficiently done in the observatories of the world generally for many years as is needed for the advancement of astronomy.

All accurate observations of the positions of the planets depend on this work and it thus becomes in some degree necessary for the further advancement of celestial mechanics. It is equally important for the solution of that greatest problem of physical science, the constitution of the visible universe, which must perhaps wait on further lapse of time and increase in accuracy of the observations of the places of the stars.

The late Professor Asaph Hall, U.S.N., was much interested in this kind of astronomical work, as may be seen by consulting the *Ast. Nach.*, No. 1692.

6. The problems treated in the paper by Professor Moulton are: (1) The theoretical shape of the sun, (2) the character and period of its possible gravitational oscillations, (3) the effects of changes of its dimensions upon its rate of rotation, (4) its energy of rotation, (5) its potential energy, (6) its temperature and rate of rotation and (7) applications of the same ideas to variable stars.

The results are: (1) the sun is oblate and the theoretical difference in its polar and equatorial diameters is less than $0''.01$. (2) Its gravita-

tional oscillations are expressible in spherical harmonics whose periods depend upon their order. Assuming the sun to be a homogeneous liquid, the longest period is 3 h. 8 m. If it has the viscosity of water this oscillation will change to 37 per cent. of its value in 2.2×10^{13} years. (3) The change of the sun's diameter by $0''.1$ will change its period of rotation by 7.8 minutes. (4) The formula was found for the change in the rotational energy. (5) The formula for the potential of spheroid of polar radius c , equatorial $c\sqrt{1+\lambda^2}$, and mass m upon itself is

$$V = \frac{3}{2}k^2 \cdot m^2/c(1 - \frac{1}{2}\lambda^2 - \frac{1}{15}\lambda^4 \dots).$$

(6) The expansion of the sun by $0''.1$ will decrease its temperature (assuming its specific heat is unity) more than $1,400^\circ \text{C}$., and if it obeys Stefan's law, diminish its radiation (assuming its temperature to be $6,000^\circ$ before expansion) by more than 65 per cent. (7) It is shown how gravitational oscillations can explain many puzzling phenomena of variable stars, such as variable periods in the so-called eclipse variables, secondary maxima and minima, varying maxima and minima, etc. It is thought that these factors are supplementary even in those cases where the binary character of the star is certain, and that perhaps in certain classes of stars they may be the only causes of variability.

7. Spectroscopic binaries of the helium type may be divided for convenience into two classes: those of long period and high eccentricity, and secondly, those whose periods are short and whose orbits are nearly circular. Mr. Baker's paper relates to the latter and much more numerous class, of which a *Virginis* is typical. This class includes a large number of Algol variables, as a special case where the orbital inclination approaches 90° , if the eclipse theory of their light variation be assumed. The following conclusions were reached: The majority of spectroscopic binaries of the helium type belong to one class, they revolve in close proximity in nearly circular orbits of short period, they are Algol variables inclined at various angles, the spectra of both components are, in general, visible and similar, and the fainter components are less massive than the brighter ones.

8. The binary character of a *Coronæ Borealis* ($\alpha = 15^h 30^m$, $\delta = +27^\circ 3'$) was discovered by Hartmann from six plates obtained at Potsdam in 1902 and 1903. The spectrum is of the type 1 a 2 in the Vogel classification.

One hundred and thirty-seven plates of this star were obtained at Allegheny Observatory between

April 2, 1907, and September 11, 1908. The emulsions used were Seed 27, Seed 23 and lantern slide. The lines K, H δ , H γ , λ 4481 and H β were the only ones measured. On the lantern slide and Seed 23 plates numerous other faint lines were visible, and in some cases measurable, but were not used. Among them are the lines λ 4128 (silicon), λ 4227 (calcium), λ 4233 (iron), λ 4352 (magnesium), λ 4472 (helium), λ 4550 (iron). A dozen other lines could be approximately located, while still others were occasionally faintly visible.

Mr. Jordan found that the total range in velocity is 69.86 km. As the periastron point is in the fourth quadrant, the ascending branch of the velocity curve is steeper than the descending. The center of gravity of the system has practically no velocity in the line of sight.

No trace of a secondary spectrum can be seen.

9. In No. 604 of the *Astronomical Journal*, published on September 25, 1908, Professor Lewis Boss communicated an important paper entitled "Convergent of a Moving Cluster in Taurus." In this he presents the evidence, derived from their proper motions, that 39 stars in or near the *Hyades* are converging upon the same point. Radial velocities have been published by Küstner for three stars of the cluster, namely, γ , δ and ϵ *Tauri*. Assuming these values to be representative of the cluster, the radial velocities of the remaining stars can be inferred. They would range from 37 to 44 km. per second. Before the article was printed Professor Boss had privately called the attention of Professor Frost to his results and to the desirability, in so far as possible, of determining the radial velocities of the stars in the cluster. He accordingly added the 41 stars to the observing program of the spectrograph, and during the present autumn they have been observed, as circumstances permitted, chiefly by Messrs. Barrett and Lee.

The spectra of most of the stars are of the first type, so that the lines are generally diffuse and suitable for only the dispersion of the single prism which has been regularly employed for them.

There has not yet been opportunity to measure these plates and this note is merely given to state that this piece of work is in progress. Thus far 60 spectrograms have been obtained of 21 of the stars, the magnitude of which are mostly between 4.5 and 5.6.

It may be said from a preliminary examination of the plates that no star contradicts in sense the value presumptive from Professor Boss's re-

searches, and in general the radial velocity appears to be of about the amount expected. Some of the spectra will hardly admit of accurate enough measurement to establish the accordance with the predicted values. This examination only indicates that the stars thus far observed are receding from the sun with velocities of about 40 km. per second. No inference can yet be reached as to the differences in radial velocity dependent upon the star's position in relation to the point of convergence.

We have been somewhat surprised at the large proportion of spectroscopic binaries already detected in this cluster. Six of those so far observed appear to be certainly of this character, and others are suspected.

The six are: *90 Tauri* and B.D. 15° 637, found by Mr. Barrett; *64 Tauri* and *97 Tauri*, found by Mr. Lee; θ *Tauri* and *69 (Upsilon) Tauri*, found by the writer. The last two had been observed before Professor Boss called attention to the cluster. θ *Tauri* has also been detected as a spectroscopic binary at the Lick Observatory. Double lines are exhibited by the first two and last three stars.

10. The paper by Messrs. Fox and Abetti presents evidence proving occasional interaction of sun-spots. On spectroheliograms obtained on September 10, 1908, regions surrounding three spot groups then just past the central meridian were observed to burst synchronously into active eruption. The eruptions progressed until the interval between the two larger groups, about 120,000 miles, was completely and brilliantly bridged. The whole display lasted less than four hours. Successive plates, shown by lantern slides, revealed the progressive stages of the demonstration.

11. It is known that on the Riemann surface associated with

$$s = \pm \sqrt{A(s-a_1)(s-a_2)(s-a_3)(s-a_4)},$$

in which a_1 and a_2 are connected by a canal as are also a_3 and a_4 , that every one-valued function of position which has everywhere a definite value is of the form

$$w = p + q \cdot s,$$

where p and q are rational functions of the complex variable s ; and reciprocally every function of the form

$$w = p + q - s$$

is a one-valued function of position on this Riemann surface. If we denote two such functions by

$$w_1 = p_1 + q_1 \cdot s, \quad w_2 = p_2 + q_2 \cdot s,$$

then the sum, difference, product and quotient of the two functions w_1 and w_2 are functions of the form

$$w = p + q \cdot s.$$

Let z take all real and complex values and consider the collectivity of all rational functions of z with arbitrary constant real or complex coefficients. These functions form a closed realm, the individual functions of which repeat themselves through the processes of addition, subtraction, multiplication and division, since clearly the sum, the difference, the product and the quotient of two or more rational functions is a rational function and consequently an individual of the realm. This realm is denoted by (z) .

It is evident that if we add (or *adjoin*) the algebraic quantity s to this realm we will have another realm, the individual functions or elements of which repeat themselves through the processes of addition, subtraction, multiplication and division. This realm includes the former realm. We shall call it the elliptic realm and denote it by (s, z) .

Owing to a theorem due to Liouville, the most general one-valued doubly periodic function is a rational function of z and s . It is consequently a one-valued function of position in the Riemann surface and belongs to the elliptic realm of rationality (z, s) .

The elliptic or doubly periodic realm of rationality (z, s) , where

$$s = \pm \sqrt{A(z-a_1)(z-a_2)(z-a_3)(z-a_4)}$$

degenerates into the simply periodic realm when any pair of branch-points are equal, say $a_1 = a_2$; and into the realm of rational functions when two pairs of branch points are equal, say $a_1 = a_2$ and $a_3 = a_4$.

Thus the elliptic realm includes the three classes of one-valued functions: (1) the rational functions, (2) the simply periodic functions, (3) the doubly periodic functions. All these one-valued functions, and only these, have algebraic addition-theorems.

In other words, all functions of the realm (z, s) have algebraic addition-theorems, and no one-valued function that does not belong to this realm has an algebraic addition-theorem.

We have thus the theorem: The one-valued functions of position on the Riemann surface

$$s^2 = A(z-a_1)(z-a_2)(z-a_3)(z-a_4)$$

belong to the closed realm (z, s) and all elements of this realm and no others have algebraic addition-theorems.

Professor Hancock's paper will be offered to the *American Journal of Mathematics* for publication.

12. The paper by Artemas Martin is devoted to an algebraic determination of the point within a triangle at which the sides subtend given angles. The paper is to appear in the *Mathematical Magazine*, which is edited by the author of this paper.

13. The paper by J. Burkitt Webb is devoted to exhibiting the advantages which would result from the adoption of a system of notation with 16 as its base. The success which has attended the movements towards a universal language has inspired the author with hope in the success of a movement towards the selection of a more useful system of notation, and he pointed out the many advantages which the base 16 would offer.

14. This paper is devoted to a discussion of a series of photographs of comet Morehouse, made at Swarthmore College by J. A. Miller and W. R. Marriott from October 2 to December 3, 1908. The comet was photographed from one to three times every clear night within that period. These photographs show remarkable and, in some instances, rapid changes in the form of the comet's tail and in the arrangement of the streamers. The most striking changes occurred on October 4; on October 15, 16, 17, 30, 31 and November 1 the changes were sufficiently rapid to enable one to measure an increase of the distance of a condensation in the tail upon photographs taken less than two hours apart.

15. The rather prevalent custom of resolving or expressing every natural phenomenon—be it periodic or otherwise—by a Bessel or a Fourier series or by spherical harmonic functions, has brought about at times, especially in geophysical and cosmical phenomena, if not direct misapplications, at least misinterpretations of the meaning and value of the derived coefficients. Instead of clarifying the situation our calculations may have actually contributed to befog it. Instead of rejecting, one must learn to consider the outstanding residuals as the *true* facts of nature and not treat them as though they were "abnormal" or contrary to nature's law.

Dr. Bauer exemplified these statements in a brief discussion of two cases that are typical in geophysical investigations—the one involving an application of spherical harmonic functions to the representation of the distribution of the earth's magnetism over the earth, while the other involved the use of Fourier series in the representation of certain diurnal geophysical phenomena.

The chief purpose of the paper was to recall

renewed attention to the limitations, from a physical standpoint, of the form of "interpolation formulæ" usually employed in the representation of natural phenomena.

16. Mr. H. W. Fisk considers the formula for latitude,

$$\phi = h - p \cos t + \frac{1}{2} p^2 \sin 1' \sin^2 t \tan h,$$

from Chauvenet's I., § 176, and the formula for azimuth,

$A = p \sin t \sec \phi + p^2 \cos \phi \tan \phi \sin t \cos t \sin 1'$, from Jordan, "Zeit und Orts-Bestimmung," p. 122. The first terms of these formulas are readily computed. The last terms, called correction terms, are arranged as a set of curves from which the value is quickly taken by inspection. The geographical limits within which this method may be used, as well as the expected accuracy under different conditions are discussed. Attention is given to the change in correction terms due to the progressive change in the value of p .

The general committee elected Professor E. W. Brown, Yale University, vice-president and chairman of the section. Professor G. A. Miller, University of Illinois, continues in office as secretary. The section elected Professor G. B. Halsted, counselor; Professor Winslow Upton, Ladd Observatory, as member of the sectional committee for five years.

G. A. MILLER,
Secretary of Section

UNIVERSITY OF ILLINOIS

SOCIETIES AND ACADEMIES

THE WASHINGTON ACADEMY OF SCIENCES

THE fifty-first meeting of the Washington Academy of Sciences was held at Hubbard Memorial Hall, January 5, 1909. Dr. L. O. Howard presided.

Dr. E. B. Poulton, F.R.S., Hope professor of zoology in the University of Oxford, delivered an address on "Recent Researches on Mimicry and Seasonal Forms of Butterflies," of which he has kindly furnished the following abstract:

The lecturer explained the theory of mimicry proposed by H. W. Bates, showing in illustration some of the figures from the plates of the original monograph read before the Linnean Society of London, November 21, 1861. In these, as in most of Bates's examples, Pierine butterflies, presumed to be palatable to enemies, were seen mimicking the unpalatable Ithomine (Heliconine) butterflies from the same localities. Succeeding illustrations exhibited oriental Pierine butterflies of the genus *Delias* acting as models instead of

mimics, and beautifully resembled by moths of the subfamily Chalcosiinae (Zygænidæ)—themselves admitted to belong to a group defended by its unpalatability. Such examples are of course inexplicable by the theory of Bates, but receive an interpretation on the hypothesis of Fritz Mueller, which supposes that the resemblance between distasteful forms has been gained in consequence of the saving of life effected by a lessened amount of experimental tasting by enemies. That the same Muellierian principle holds in other groups is seen in the numerous and varied distasteful forms which mimic the African Lycid beetles and by resemblances between well-defined wasps of different groups in the same locality.

The alternative between a Batesian and Muellierian interpretation may be approached from another point of view. In the case of a distasteful butterfly invading a new country we may enquire whether the indigenous species influenced by it are well concealed and presumably palatable, or conspicuous and presumably distasteful. The two large Danainæ of North America are especially interesting from this point of view. Formerly placed by Moore in two genera peculiar to the new world, *Anosia* and *Tasitia*, recent examination has shown that they are congeneric with each other and with the more dominant old world *Salatura* and *Limnas*. All four genera certainly sink to *Danaida*. The old world forms are more numerous and are far more extensively mimicked than those of the new. They, furthermore, enter into mimetic relations with other *Danainæ*. The American species of *Danaida*, on the other hand, are only mimicked by a single Nymphaline species in the north. They extend through South America beyond the southern tropic without entering into any relationship with the indigenous butterfly fauna, except the possible incipient mimicry of a form of *D. pleippus* by an *Actinote*, one of the *Acræinæ*. It may be inferred from these facts that *Danaida* is an old world Danaine genus which has reached the new world in comparatively recent times and has entered South America by way of North America.

The well-known mimic of *D. pleippus*, *Basilarchia* (*Limenitis*) *archippus* has been evolved from *B. (L.) arthemis*—with a pattern of the *Limenitis* type found through the temperate circumpolar belt. In the theory of the production of mimetic resemblance by climatic or other local influences the invading Danaine should have been influenced to produce a *Limenitis* pattern in the northern temperate zone. It should have been the mimic instead of the model. The black and white

pattern and conspicuous surface of the form (*B. phemias*) which has been influenced supports strongly the Muellierian hypothesis. The mimic has in fact exchanged its original conspicuous pattern similar to that of the invading *Danaeus*.

Danaida derenice of Florida is probably a later invader than *plexippus* and has modified into resemblance with itself the mimic already formed under the influence of this last-named *Danaeus*. But the change is so recent that distant traces of the original mimicry of *plexippus* are easily seen in the *floridensis* (= *eros*) form of *archippus*.

Evidence in favor of the Muellierian hypothesis is also to be found in the complex group of mimetic butterflies which are ranged round the North American *Papilio* (*Pharmacophagus*) *philenor*. The female of *Papilio asterius*, a female form of *P. glaucus* (= *turnus*), and both male and female of *P. troilus* form primary mimics of *philenor*, but also appear to exhibit an evident secondary approach towards one another. *Basilarchia* (*Limenitis*) *astyanax*, considered by Haase as a mimic of *philenor*, is rather to be interpreted as a secondary mimic of the three mimetic swallow-tails. The female of *Argynnis* (*Semnopsepsyche*) *diana*, also thought by Haase to be a mimic of *philenor*, certainly resembles *B. (L.) astyanax*, as was clearly stated by Scudder. It is therefore a tertiary mimic. These complex resemblances to mimics and even to mimics of mimics rather than to the central model, are intelligible on the hypothesis of Fritz Mueller and not on that of H. W. Bates.

The concluding section of the address dealt with recent additions to our knowledge of the complex phenomena of mimicry in the females of the African *Papilio dardanus* (= *merope*), and with seasonal changes in African Nymphaline butterflies. A representation of a family of 28 individuals bred from the eggs laid by a *hippocoon* female of the South African *P. dardanus cenea* was thrown upon the screen. The family consisted of 14 non-mimetic males, 3 *hippocoon* females, like the parent, mimicking the *Danaeus* *Amauris niavius dominicanus*; 3 *trophontus* females, mimicking *Danaida chrysippus*; and 8 *cenea* females, in part mimicking *Amauris albimaculata* and in part *Amauris coheria*. The recently described *flammoides* female form of the tropical subspecies of *dardanus*, extending from Nairobi westward to the Atlantic, was also represented. This is the only form which resembles a model other than a *Danaeus*—the *Acræine* *Planocina foggel*. The evolution of the mimetic forms of *dardanus* from a non-mimetic female like that

of the Abyssinian *P. antinorii* or the Madagascar *P. meriones* was shown to be readily intelligible through the intermediate form *trimeni* from the Kitnya escarpment.

In addition to the seasonal forms of the African species of *Precis*—*sesamus*, *antelope*, *actia*, *archesia* and *artaxia*, the recent evidence that similar changes may occur in the genus *Charaxes* was described and illustrated on the screen. A family of individuals bred from eggs laid by *Charaxes neanthes* contained one specimen of *O. sootina*. This fact confirmed and placed beyond controversy the evidence that had long been accumulating that these are but forms of a single species.

This interesting and conclusive evidence has been obtained at Durban, Natal, by Mr. G. F. Leigh, who also bred the large family of *P. dardanus*, already referred to. The conclusions as to the seasonal forms of *Precis* are founded on the specimens bred by Mr. Guy A. K. Marshall at Salisbury, Mashonaland.

J. S. DILLIE,
Recording Secretary

THE BOTANICAL SOCIETY OF WASHINGTON

THE 50th regular meeting of the society was held on November 21, 1908, Vice-president Thos. H. Kearney presiding. The following papers were read:

Plant Breeding in England and Sweden: Dr. ALBERT MANN.

Dr. Mann's paper, which was illustrated by a number of excellent lantern slides, treated chiefly of the methods of culture of barley, as observed by him during a recent trip to England and Sweden. In England he visited Mr. Beaven, of Warminster; Professor Biffen, of Cambridge, and John Garton, of Warrington. His observations showed that English barley culture is carried to much higher perfection than in the United States; that two-row barley, except in yield, is generally preferred; and that pedigree stock is the only source of permanent grain improvement. At Svalof, Sweden, an ingenious system of classification and original methods of breeding have produced remarkable results. The two chief ideas of Svalof, namely, the securing of new varieties by selection from old land races and the production of pure pedigree stock by growing such from a single mother plant were fully discussed and in general heartily commended. Information of minor importance was secured from Professor de Vries, of Amsterdam; Professor Johannsen, of Copenhagen; Professor von Tschermak, of Vienna,

and Professor Kraus, of Munich. The relative lack of information in the United States as to work done by European barley-growers was in strong contrast to the accurate data possessed by them in regard to work in this country. Mr. E. S. Beaven, of Warminster, not only knew definitely the quality and yield of all our American barleys, but he also had samples of every variety from every section of this country. This spirit of progressiveness is deserving of our attention. Mr. Beaven spoke highly of our California brewing barley, but he had a less favorable opinion of our other grades, especially of some now grown in the northwest.

The use of Timbe Barks by the Mexicans in the preparation of Alcoholic Drinks: W. E. SAFFORD.

Timbe, or timbre, is a name applied to certain barks and roots offered for sale in the markets of San Luis Potosí and several other Mexican cities for use in the manufacture of pulque. They have a bitter astringent taste and evidently abound in tannic acid. On the Pacific coast of tropical Mexico the same name is applied to certain barks used in tanning leather. The identity of the principal timbes has not hitherto been established and the part they play in the manufacture of pulque has not been understood. Among the most important plants from which they are obtained are *Acacia flioides*, the principal source of the San Luis Potosí supply, and a sumach, *Rhus paohyrrachis*. Other barks used for a similar purpose are those of *Calliandra grandiflora* and *Calliandra Houstoni*, the latter of which is also used extensively by the Mexicans as a cure for intermittent fever, under the name of pambotano. At first the sap of the agave from which pulque is made is sweet and clear. It is sold about the streets in this condition under the name of *aguamiel* (honey-water). It soon begins to ferment spontaneously and becomes milky and finally stringy, acquiring a putrid smell, if unchecked, from the fermentation caused by the lactic-acid bacteria contained in it. The timbe bark, after having been toasted and pounded, is added to the sap about four hours after the fermentation has begun. It has the effect of precipitating the greater portion of mucilaginous substances held in solution, undoubtedly owing to the action of the tannic acid in the bark upon the proteids, which, if let alone, would cause the liquid to putrify or turn sour. Its action, then, may be compared to that of hops in the manufacture of beer, which probably do not destroy the lactic

bacteria, but cause the precipitation of albuminous material. In addition to this the timbe imparts a pleasant bitter taste to the drink.

W. E. SAFFORD,
Corresponding Secretary

THE TORREY BOTANICAL CLUB

THE meeting of November 25, 1908, was called to order at the museum building of the New York Botanical Garden at 3:40 P.M., with Dr. M. A. Howe in the chair. Fourteen persons were present. The minutes of the meeting of November 10 were read and approved.

The resignation of Dr. Valery Havard, dated November 8, 1908, was read. A motion was made and carried that the resignation of Dr. Havard be accepted and that his name be transferred to the list of corresponding members.

There was no announced scientific program for this meeting, but the following communications were made:

Dr. Britton showed fruits of the rare and local tree, *Prioria copaifera* Griseb., which he collected, in company with Mr. William Harris, at Bachelor's Hall, Jamaica, near where it was originally discovered sixty years ago by Nathaniel Wilson, who sent it to Grisebach. *Prioria* is one of the largest trees of Jamaica, sometimes attaining a height of ninety feet, and is a member of the senna family. So far as is known, this tree is found only on two estates in Jamaica, and grows at an elevation of from five to six hundred feet. This species is characterized by having a one-seeded legume, which is indehiscent. The genus *Prioria* is reported to be represented also in the Republic of Panama.

Dr. Murrill displayed photographs and colored drawings of several of the larger local fungi. He also explained reproduction of colored drawings by the four-color process. This process seems to be the most satisfactory for representing fungi in colors.

Mr. Nash exhibited a living plant of *Dendrobium Oeologyne*, a rare orchid from Burma, which has just flowered in the conservatories of the New York Botanical Garden. Specimens of *Oeologyne* and of other species of *Dendrobium* were also shown to illustrate the characters of these two genera. While the flowers of *Dendrobium Oeologyne* resemble those of a *Dendrobium*, the habit is that of a *Oeologyne*.

THE INFLUENCE OF THE MATERIAL OF WIND-INSTRUMENTS ON THE TONE QUALITY¹

SOUND is the sensation resulting from the action of an external stimulus on the sensitive nerve apparatus of the ear; it is a species of reaction against this external stimulus, peculiar to the ear, excitable in no other organ of the body, and completely distinct from the sensations of any other sense.

Atmospheric vibration is the normal and usual means of excitement for the ear, this vibration being produced directly in some instruments, called wind-instruments, and indirectly through the vibration of elastic bodies in others, such as string and percussion instruments; and often the vibration originates in bodies not especially designed for producing sounds.

Physics is mainly concerned with the nature of the external stimulus, and the word sound is often restricted to refer only to these external stimuli. But the purely mechanical properties of these stimuli often differ among themselves differently than do the auditory effects. Our interest is largely in relation to musical sounds and hence for the present investigation we are concerned with the properties of the sounds of mechanical physics only in so far as they affect the ear, or produce sensation. We may, therefore, define sound substantially in the words of Helmholtz, as already given, and proceed

¹ Address of the vice-president and chairman of Section B, American Association for the Advancement of Science, delivered December 29, 1908.

to investigate the physical cause of these sensations.

If we investigate how many kinds of sensation the ear can generate, we find that, either because of fundamental or acquired distinctions, the ear divides sounds roughly into two main classes, noises and musical tones. Helmholtz's distinction between tone and noise, that one is periodic and the other non-periodic, in the light of recent experiments, seems hardly adequate. Analysis clearly shows that many musical tones are non-periodic, at least in the sense intended; and it is equally certain that noises are as nearly periodic as are some tones. In some instances noises are due to a rapidly changing period, causing non-periodicity; but by far the greater number of noises, which are continuous, are merely complex and only apparently irregular; their analysis is difficult or impossible. The ear, often because of lack of training, or the absence of suitable standards for comparison, or perhaps on account of fatigue, fails to appreciate the relations between certain sounds, and, resigning its attention, classes the sounds as noises. The study of noises is essential to the understanding of the qualities of musical instruments, and especially of speech; but their study may well be passed till we more completely understand the nature of the apparently simpler, and much more interesting, musical tones. While actual musical tones may be non-periodic, containing incommensurable partial tones, yet it is probable that the components are individually periodic, and often the entire tone is periodic. We may proceed with the provisional definition that the sensation of tone is caused by a periodic vibration in the air, and to this we are mainly to confine our attention.

The ear, further, receives three classes of sensations from tones, and presumably no more. One of these gives rise to the

characteristic of the tone called pitch; this is easily proven to depend upon a very simple condition, that of mere frequency of vibration.

The second property of tone is loudness or intensity, which is not so simple as pitch. For tones of the same pitch, it varies mainly as the energy of vibration, and this is a function of the amplitude of vibration, varying approximately as its square; loudness also varies with pitch, approximately as the square of the frequency. As regards the loudness of what we hear, very much depends upon the individual ear, and, as Professor Sabine has clearly shown, upon the surrounding objects, walls of rooms, etc.

The third property of tone is much the most complicated; it is that characteristic of sounds produced from some particular instrument or voice, by which they are distinguished from the sounds of the same loudness and pitch, produced from other instruments or voices. This characteristic is called timbre, clang-tint, *klangfarbe*, or, best of all, the idea is expressed by the simple English word quality; we shall use the word quality in this specific sense.

With comparatively little practise any one can acquire the ability to distinguish with great ease any one of a long series of musical instruments, even when they all sound tones of the same loudness and pitch. There is an almost infinite variety of tone quality; not only do different instruments have characteristic qualities, but different individual instruments of the same family show more delicate shades of tone quality; and even notes of the same pitch can be sounded on a single instrument with qualitative variations. The bowed instruments, of the violin family, show this ability in a marked degree. But no musical instrument equals the human voice in the richness of qualitative va-

rieties and variations; speech employs these very qualitative varieties to distinguish the letters and syllables.

When we inquire as to the cause of tone quality, since pitch depends upon frequency and loudness upon amplitude, we conclude that quality must depend upon the only remaining property of a periodic vibration, namely, the peculiar kind or form of the motion; or, if we represent the vibration by a curve or wave line, the quality is dependent upon the peculiarities represented by the shape of the wave. There is possible an endless variety of motion for the production of sound, and quality is, therefore, almost infinitely complicated in its causes, as compared with the other two properties of sounds.

There can not be a simpler mode of vibration than that known as simple harmonic motion, which is represented by the wave line called the sine curve; such motion is often referred to as pendular motion. Tuning forks properly constructed and mounted on resonance boxes are shown by analysis to produce vibrations in the air which are single simple harmonic motions; the resulting tones are called simple tones, and their sensation is markedly simple and pure. If several simple tones of different pitches, as from several tuning forks, are simultaneously sounded, they simultaneously excite different systems of waves, which exist as variations in density of the air; the resulting displacements, velocities, and changes in density of the air are each equal to the algebraic sum of the corresponding displacements, velocities and changes in density which each system of waves would have separately produced had it acted independently. There must, therefore, be peculiarities in the motion of a single particle of air which differ for a single tone and for a combination of tones; and in fact the kind of motion during any

one period is entirely arbitrary, and may indeed be infinitely various.

The method by which the ear proceeds in its analysis of tone quality was first definitely stated by Ohm, in Ohm's law of acoustics. Helmholtz states this law in the following forms:

All musical tones, however complex or peculiar in quality, are periodic; the human ear perceives pendular vibrations alone as simple tones, and it resolves all other periodic motions of the air into a series of pendular vibrations, *hearing* the series of simple tones which correspond to these simple vibrations.

Another rendering of this law is:

Every motion of the air which corresponds to a composite mass of musical tones is capable of being analyzed into a sum of simple pendular vibrations, and to each such simple vibration corresponds a simple tone, sensible to the ear, and having a pitch determined by the periodic time of the corresponding motion of the air.

The separate component tones are called partial tones, or simply partials; that partial having the lowest frequency is the fundamental, while the others are overtones. However, it sometimes happens that a partial not the lowest in frequency is so predominant as to give the main character to the whole sound, and it may be mistaken for the fundamental. If the overtones have frequencies which are exact multiples of the frequency of the fundamental, they are often called harmonics; otherwise they may be designated as inharmonic partials.

In stating his law, in 1843, Ohm says:

Fourier spread light in our darkness when he brought out (in 1822) his work "*La Théorie Analytique de la Chaleur*," and so enabled theoretical mechanics to solve the most difficult problems of physics with unparalleled ease.

Fourier had shown in a purely mathematical way, and with no idea of acoustical application, that any given regular periodic function can always be expanded in a trigonometric series of sines and cosines, and for each case in one single way only.

Each sine or cosine term in the series may be considered as representing a single vibration; then in Fourier's series, the successive terms have frequencies which are exact multiples of the first, but the amplitudes and phase differences are arbitrary and can always be found in every given case, by peculiar methods of calculation which Fourier has shown.

So far as Fourier's theorem is concerned this method of analyzing sound vibrations might be merely a mathematical form, not necessarily having any corresponding actual meaning in the sounds themselves. Moreover, in actual musical sounds, many of the important partials are not exact multiples of the fundamental in frequency, that is, they are inharmonic, and with these Fourier's theorem has nothing whatever to do, although Ohm's law still applies to them.

Helmholtz fully demonstrates that the ear unaided can thus analyze tones; he also developed several methods for assisting the ear, chiefly by the use of resonators. His monumental work, "*Tonenempfindungen*," was referred to by our chairman last year as

produced by a masterful knowledge of physiology, physics and mathematics, and a scholar's knowledge of the literature of music, remarkable for its breadth, completeness and wealth of detail.

A large part of this work is concerned with the demonstrations of Ohm's law that the quality of a musical sound is dependent upon the particular combination of partial tones which make up the sound under examination. He held that

Differences in musical quality of tone depend solely on the presence and strength of partial tones, and in no respect on the difference in phase under which these partial tones enter into composition.

A few historical references may be interesting as showing how clearly these ideas were perceived by the earliest investigators.

Descartes (1618) says:

No musical sound can be heard which does not appear to the ear to be accompanied by the octave above it.

Mersenne (1636) says of Aristotle:

He seems to have been ignorant of the fact that every string produces five or more different sounds at the same time, the strongest of which is called the natural tone of the string, and alone is accustomed to be taken notice of, for the others are so feeble that they are perceptible only to delicate ears.

Perrault (1680) says:

Every noise, although apparently simple, is in effect a system and an assemblage of an infinity of partial noises that compose a total, in which no confusion is remarked on account of the affinity that all these partial noises have together.

Sauver (1702) remarks that

The organ only imitates by the combination of its stops the natural harmony of sonorous bodies.

La Grange and Bernoulli (1760) both state clearly the cause of quality:

The same single sonorous ray may be moved at the same time by many species of vibrations which do not interfere with each other in any manner; in the place of a node with regard to one species, a segment may be formed with regard to another.

Monge (1800) says that

Quality is due to the order and number of the vibrations of the aliquot parts of a string, and if the vibrations of these aliquot parts could be suppressed, all strings, of whatever material, would yield tones of the same quality.

Young (1800), describing his experiments for rendering visible the vibrations of a string by means of a ray of light, says:

According to the various modes of applying the bow an immense variety of orbits are produced; more than enough to account for all the differences of tone by different performers.

Biot (1817) says:

All sonorous bodies yield simultaneously an infinite number of sounds of gradually decreasing intensity, but the law for the series of harmonics is different for bodies of different forms; it is this difference which produces the particular character of sound called timbre. And may not the quality of each particular substance, wood or metal, for

instance, be due to the superior intensity of one or another harmonic?

Many other quotations might be given of opinions expressed by Rameau, Chladni, Wheatstone and others; but enough has been said to show that the ideas as to quality were well understood before Ohm put forth his law, which is almost misnamed.

Helmholtz (1862) defended and developed Ohm's theorem, and gave elaborate proof of it, chiefly by the use of resonators. Melde (1864) made visible, by his beautiful tuning-fork monochord, the simultaneous existence of two or more harmonic vibrations in a string. Koenig (1872) showed the simultaneous coexistence of two sets of waves in the same organ pipe by means of his manometric flames.

The theories of Ohm and Helmholtz seem so simple that they have generally been accepted as expressing the whole physical condition, and few investigators have successfully combated them. Seebeck (1844) argued that the quality of tone must be decided by the ear, and he concluded that the definition of a simple tone given by Ohm is too limited; he believes that other forms of vibration besides the pendular are capable of giving the sensations of a single simple tone, and that simple tones may have different qualities among themselves. Seebeck greatly improved the siren, and used it to produce the fundamental and partial tones with which he experimented. Helmholtz admits the experimental results of Seebeck, and after extended argument, he claims that Seebeck did not give proper attention to the hearing of the partials.

Another investigator to oppose Helmholtz was Koenig; he was not satisfied with the statement as to the cause of tone-quality. Koenig invented the wave siren, a very beautiful piece of demonstration apparatus, with which he showed that quality is not accounted for solely by the presence and relative intensity of the partials;

but that phase is a factor too important to be left out of account. If changes in the number and intensity of the partials give rise to such differences in quality as we observe in instruments belonging to different families, Koenig says the changes in the difference of phase for the same partials are competent to produce differences of quality at least as sensible as those which are noticed in instruments of the same kind.

Helmholtz says distinctly that if we disregard the noise of rushing wind, the proper musical quality of the tone produced by blowing over the mouth of a bottle is really the same as that produced by a tuning fork; and that the tone of a flute, which according to Helmholtz is practically devoid of over-tones, is the same as that of a tuning fork. Since we agree to some extent with Seebeck, that tone quality must be decided by the ear, we hesitate to adopt the conclusion that the bottle and the fork both give simple tones of the same musical quality.

When this address was first thought of, it was hoped that some conclusions might be reached regarding this general question. But, for reasons referred to later, it seems best to limit our further consideration to certain particular instances, about which it is believed some definite conclusions can be drawn.

Perhaps the points to be investigated will be most clearly presented by a somewhat personal statement of the incidents that led to this enquiry.

In connection with the study of the flute as a musical instrument there arose the question which may be specifically stated:

Is the tone quality of a flute, the tube of which is made of gold, superior to that of a similar flute having a tube of silver or of wood? If there is a difference, what is its cause?

Probably many will be inclined at once to dismiss the subject as not a question,

claiming that there can be no difference in such a case, due to material. The writer was of this opinion at one time. When visiting the establishment of an eminent London flute maker, in 1900, he was shown several flutes which were tested. One instrument seemed of such unusual excellence that the remark was made that it was certainly of the finest quality of any that had ever been tried. After the instrument had been returned to its case, the writer enquired whether it would be possible, at some time in the visit to London, for him to see one of the few gold flutes which had been made, and which were celebrated for quality. The reply was startlingly unexpected, for the maker said, with evident satisfaction, that the flute just played was of gold! It had been prepared for the Paris Exposition, but was not being exhibited, as the English exhibits had been largely withdrawn because of some French caricatures of Queen Victoria. It may be well, also, to add that the flute had been examined in dim artificial light, the color thus escaping notice. However, the incident carried conviction to the writer, as very few tests could have done.

As further justification for considering this question, several quotations will be given showing the great difference of opinion among those who should speak with authority.

Each kind of wind instrument, except the flute, has always been made of its own proper kind of material; there are two large classes, the wood-wind and the brass-wind of the orchestra. Each group has its distinct tone quality, which is generally considered as due to the method of tone production, while the material is regarded as a matter of mechanical convenience. The flute is classified as a wood-wind instrument.

Formerly flutes were usually made of wood, though in 1806 flutes of glass were

patented by Laurent, of Paris, the advantages claimed being, not tone-quality, but freedom from checking, changes of bore, and leakage. Ivory has been used for small flutes, and parts of large flutes, mainly for the sake of appearance. In 1847 Theobald Boehm, of Munich, a Royal Bavarian court-musician, who had, in 1832, invented a new system of fingering and key construction, made elaborate experiments on the bore, size of holes, and material. These experiments had an academic relationship, for they were carried out under the guidance of Dr. Carl von Schafhäütl, an eminent professor in the University of Munich, who was a life-long personal friend of Boehm. Boehm experimented with hundreds of tubes, and our interest lies in the fact that he introduced with great success cylindrical tubes of hard-drawn silver, though wood tubes were also used. There at once arose a controversy as to the relative merits of various materials, which still rages.

Besides being one of the world's greatest artists and a composer of ability, Boehm maintained one of the most celebrated flute manufactories, and made hundreds of flutes of the highest excellence; instruments made in his lifetime are to-day valued above all others, as the old Italian violins are valued above modern instruments. Near the end of his career, in 1871, he published a book giving the results of his sixty years of experience, in which he says:

The greater or less hardness and brittleness of the material has a very great effect upon the quality of tone. Upon this point much experience is at hand. Tubes of pewter give the softest, and at the same time the weakest, tones; those made of very hard and brittle German silver have, on the contrary, the most brilliant, but also the shrillest, tones; the silver flute is preferable because of its great ability for tone modulation and for its unsurpassed brilliancy and sonorousness; compared with these the tones of flutes made of wood, sound literally wooden.

Directly against these opinions of Boehm we may place the equally authoritative one of Victor C. Mahillon, of Brussels, the head of the celebrated musical instrument manufactory, and the Curator of the Museum of Instruments of the Belgian Royal Conservatory of Music—containing one of the most celebrated collections of musical instruments in the world. Mahillon has devoted his life to the study of musical instruments, and is recognized the world over as an eminent authority. In his treatise, “*Elements d’Acoustique, musicale et instrumentale*,” one of the best works on the acoustics of musical instruments, he says:

Theobald Boehm was the first, we believe, to try to construct a flute upon scientific principles, using a cylindrical tube, with rationally placed holes; it was he who first tried to explain the division of the air column of the tube. . . . It is to be regretted that this celebrated reformer of the flute was not able to grasp the principle, resulting moreover from his own theory, that the air is the only vibrating body in the flute, as well as in all other wind-instruments. It would have been better had he not written the following lines, which in our opinion, disfigure all of his work.

Mahillon then quotes Boehm’s opinions given above, and continues:

One would almost refuse to believe, if it were not written, that a man of the standing of Boehm, who had revolutionized, from the foundation, the principles which had existed for ages in the construction of flutes, was not able to release himself completely from such prejudices; nevertheless, he held to this one blunder.

In another place, Mahillon says:

This error is shared in by nearly all artists who play wind instruments. The one who plays a brass instrument will say that the thinner the walls the more easy will be the production of tone; the bassoonist is persuaded that all the vibrations of his instrument exist in the material of the mouth piece.

He describes the opinion of the clarionetist and flutist at length, and continues:

Who does not know the brilliant sound of the cavalry trumpet? It would seem that if this

same brilliancy were produced by an instrument constructed wholly of wood, that this error whose existence we regret, would disappear forever. But it is not so. For more than ten years, we have had occasion to make heard, almost every day, an instrument constructed by Mr. C. Mahillon; it possesses the exact proportions of a cavalry trumpet, and gives exactly the same brilliancy as the instrument of brass, so that it is impossible to distinguish the one from the other. How much trouble professors might spare their pupils, if, being inspired by the revelations of science, they would content themselves with teaching principles, and abandon the prejudices which pass every day from master to pupil.

Albert Lavignac, professor in the Paris Conservatory of Music, in his book, “*Music and Musicians*,” published in New York in 1899, says:

First we have to notice that the sonorous body is the column of air contained inside the tube, whose metal, wood, or other material, has no office whatever, except that of determining the form and dimensions of the mass of air imprisoned within it, which is itself, and itself alone, the vibrating body. The recognition of this fact is of the highest importance in understanding the subject.

Lavignac then describes the experiments of Mahillon with the wood trumpet, and other experiments of the same import by Sax, the instrument maker of Paris, with brass clarionets; he also refers to pasteboard organ pipes and other instances, which support his theory.

The gentlemen quoted are by no means alone in their opinions. The writer has occasionally mentioned to some of his scientific friends that he sometimes wondered whether the tone of a flute is affected by the material of its tube. Many times the answer has been: “Of course, *you* think it is not.”

In direct opposition to the experiments of Mahillon and Sax are those of Schafhäütl (of the University of Munich), who throughout his life made many researches on acoustical subjects, being influenced, no doubt, by the problems which his friend

Boehm was trying to solve. He is the author of many papers, which appeared in the *Annalen der Physik*, and in various scientific and musical journals. One of his papers, published in 1879, is entitled: "Is the dogma of the effect of the material out of which a wind-instrument is made, upon the tone of the same, a fable?" Schafhäütl quotes at length a sarcastic statement which begins by saying:

A fable, the more remarkable since it is always discussed, is that the material of which a wind-instrument is made, has an influence upon the material of the same; that this is not so rests upon incontrovertible acoustical laws, about which there should be absolutely no more discussion.

Schafhäütl then says:

From the student of nature, such an oracular speech in the name of science would certainly win a laugh.

He proposes to allow nature to speak for herself upon this interesting question. He then describes with great detail how he had made seven cavalry trumpets with internal dimensions all exactly alike; of thick brass, thin brass, lead, gypsum, and three of paper of different thicknesses; they were placed side by side on a convenient stand, and were blown by a most skillful professional trumpeter. He says:

What a difference in the tone quality! The most brilliant tone was given by the trumpet of brass 0.85 mm. thick. The tone of the trumpet of lead was heavy and dull, while the tone of the paper trumpets was papery and excited general laughter.

He describes many other experiments and opinions about reed instruments, violins, flutes, organs, the human voice, etc. The study of this work led the writer to repeat some of Schafhäütl's experiments and to try others with organ pipes, the results of which will be given in some detail.

For a model an open organ pipe of wood was chosen, of the style usually supplied by Koenig for acoustical experiments. This pipe gives the tone $G_2 = 192$ com-

plete vibrations—this is violin G, below middle C; the pipe is 5.8 cm. wide, 7 cm. deep, 78 cm. long and has walls 1 cm. thick. Four pipes having exactly the same internal dimensions as this wood pipe were made of common sheet zinc, the metal being about 0.5 mm. thick. Upon blowing one of the zinc pipes, the unexpected result was obtained that its pitch is more than two semi-tones of the musical scale lower than that of the wood pipe of the same dimensions; its pitch was found to be 164, and that of the other zinc pipes was nearly the same. The pipes are always blown on a windchest, under moderate pressure— $2\frac{1}{2}$ to $3\frac{1}{2}$ inches by the water gauge—which is automatically controlled.

While the zinc pipe is clearly sounding its fundamental tone, if it is very lightly touched on opposite sides by the thumb and finger, it immediately speaks the first overtone very clearly with no perceptible admixture of the fundamental; upon removal of the fingers the sound returns to the fundamental. The overtone thus obtained is not harmonic, its frequency being 2.06 times that of the fundamental; however, the pitch of both the fundamental and the overtone can be varied several vibrations per second by grasping the pipe in the hand and varying the pressure of the grasp.

If the pipe is firmly grasped in both hands, just above the mouth, it speaks a mixture of the fundamental and the second partial, just mentioned and also a third partial whose frequency is 2.66 times that of the fundamental. By increasing the pressure of the hands on the outside of the pipe, the first and second partials become weaker, while the third becomes stronger till it is the real tone of the pipe; it is approximately the tone Bb, a fourth above the octave of the fundamental. These results are so conspicuous as to be almost startling, caused by the unmusical sound of the inharmonic partials; the tone quality

varies as much as from a flute to a tin horn.

One of the zinc pipes was placed inside of a large pipe of zinc to form a double-walled pipe, with spaces 2 cm. wide between the walls; the outer wall was attached to the inner one only at the extreme bottom on three sides, but just above the upper lip plate on the front side. Attaching the outer pipe did not alter the pitch or quality in any noticeable degree. The double-walled pipe gives a full fundamental tone, $F_2 = 164$, without conspicuous overtones.

While the pipe is sounding continuously, water, at room temperature, is allowed slowly to run into the space between the walls. As this space is filling, the tone of the pipe changes conspicuously thirty or forty times; a few of these changes will be noted. When the water is 5 cm. above the lower lip, the pitch rises by 2 vibrations per second; when the water is 10 cm. high, the fundamental tone breaks, and the first overtone is clearly heard; at 11 cm. the fundamental is almost inaudible, the first overtone being loud; at 14 cm. the fundamental alone is heard, but with a pitch 6 vibrations sharper than at first. As the water rises the pitch begins to fall, and the overtone reappears, till, at a height of water of 28 cm., the two tones are both very distinctly heard, the fundamental having a pitch of $164 F_2$, the same as at the beginning, and the overtone a pitch 2.13 times as great, about that of the tone F_3 . At a height of water of 29.5 cm. the overtone is heard alone, at 31.5 cm. the fundamental only is heard; while at 33.5 cm. the two tones are mixed and are both clearly sounded. These alternations are again repeated, and as the water rises to a height of 46 cm. the fundamental begins to flatten, till, at 57 cm., its pitch is 158, that of the tone E_2 , a semi-tone lower than at first. As the pitch of the fundamental falls, that of the overtone rises, and when the water stands 69 cm. high, the fundamental has a

pitch of 160, the overtone 400, the ratio is 2:5, or the tones, instead of being an octave apart, are an octave and a third. The actual sounds are E_2 and G_3 , and the two sounds from the one pipe are each as clear and distinct as the sounds from two separate pipes, as actual comparison has many times proved to various observers. As the water rises through the remaining 9 cm., there are several changes in quality; when the space is full of water the overtone, though present, is less intense and is not in such good tune.

This pipe, which has the dimensions of a wood pipe giving the tone G, has, when empty, the pitch F, and when filled with water the pitch is E; during the filling the pitch varies more than a semi-tone, first rising and then falling, while the changes in the quality of the tone are so astonishing that they must be heard to be appreciated.

The pipe has been filled with sand, and it shows the same series of changes, though some of the tones seem to be more deadened than with the water filling, and it does not seem to be quite so sensitive to slight variations.

(Some photographic records of the variations in the sound waves coming from this pipe, and the pipe itself will be exhibited in another communication to the program of this meeting. The photographs show the distinctness of the changes that occur.)

It is, of course, well known that the pitch and even the quality of a pipe are influenced by the thickness of wall and condition of the inner surface; but that the properties of the pipe should be so profoundly altered by even slight changes entirely outside of the pipe was wholly unexpected, even with a pipe of the construction described. After the demonstration of these effects, one will surely admit that the quality of a wind-instrument may be affected by the material of its body to the comparatively limited extent claimed

by the player. That the flute is more susceptible to this influence than other instruments is due to the fact that its tube is only from 0.2 to 0.3 mm. thick, that is, half as thick as the zinc walls of the experimental pipe. The cylindrical shape of the tube gives a mechanical stiffness which largely prevents the transmission of influences through the walls; nevertheless, it is conceivable that the presence or absence of a ferrule or of some support for a key might cause the appearance or disappearance of a partial tone, or put a harmonic partial slightly out of tune. (The idea of experimenting with a flute of rectangular cross-section occurred too late to be made use of at this time.)

The traditional influences of the different metals on the flute are consistent with the experimental results obtained from the organ pipe. Brass and German silver are usually so hard, brittle and stiff as to have but little influence upon the air column, and the tone is said to be hard and trumpet-like. Silver is heavier and softer, and adds to the mellowness of the tone. The much greater softness and density of gold adds still more to the soft-massiveness of the walls, giving an approach to the organ pipe surrounded by water, and permitting a greater influence of the walls upon the tone, and increasing the richness of tone by augmenting the fullness of the partials, as was the case with the organ pipe. That the partials from the gold flute are actually fuller than from other, is proved by the photographic comparisons of wave forms which are referred to in another communication.

Mere massiveness of the walls does not fulfill the desired condition; a heavy tube, obtained from thick walls of brass, has such increased rigidity as to produce an undesirable result. The walls must be thin, soft and flexible, and be made relatively massive by increasing the density of the material.

A tube of pure platinum would best fulfill these conditions; a report upon the influence of such a tube may be made later.

The gold flute tube and the organ pipe surrounded with water are, no doubt, similar to the longer strings of the pianoforte which have such rich quality; these strings are wound or loaded, making them massive, while the flexibility or "softness" is unimpaired. The organ pipe partly filled with water is like a string unequally loaded, its partials are out of tune and give a freak tone. The flute, unfortunately of necessity, is unequally loaded by its key mechanism, and this no doubt accounts for the fact always noticed by players, that certain tones are full while others are poor or dull in quality, or are liable to shrillness; the skillful player covers these defects by his art. This opinion is confirmed by the fact that the tone of flute tubes having no holes or keys is influenced by the manner of holding the tube in the hands; certain overtones are difficult to produce till the points of support of the tube have been shifted.

(The question has been answered to the writer's complete satisfaction by actual musical trials, extending over four years, with flutes of wood, hard rubber, glass, brass, German silver, silver and gold. The gold flute is, beyond all doubt, distinctly superior; its tone may be described as full, rich, less shrill when sounded loudly, and more liquid; the silver flute is more delicate, and certainly simpler in quality, which manifests itself as shrillness in the loud and high tones.)

The quantitative and photographic investigation of this question is not complete, but one result of general application seems conclusive. Perhaps the theory of Helmholtz has been very generally accepted, that all tones of the same quality, that is, belonging to the same register of any given instrument, have a characteristic set of harmonics, the proportional intensities of

which remain constant. Visual and photographic observation of the wave forms from many instruments shows that the overtones are certainly not harmonic in the sense commonly understood, and, moreover, the different notes in the scale of any one instrument are not similar in their composition. While a tone is being given with no variation that the ear detects, the partials are seen to be rapidly varying in phase, or intensity, or both. A slight change in the manner of blowing a wind instrument, which to the ear results merely in a change of loudness, completely alters the form of the wave. Instead of a characteristic series of harmonics, it seems that each instrument possesses rather a characteristic tone or tones, which is of constant pitch for all notes of its scale. This theory has been recently advanced by Meissner, from experiments with the phonograph. Such a characteristic tone for the flute would seem to be consistent with the rather anomalous conditions imposed by the stopper in the head-joint of the instrument.

The inadequacy of the former theory is clearly shown by the failure of many attempts to synthetically reproduce the characteristic tones of orchestral instruments, such as those by Helmholtz, Koenig and more recently by the Telharmonium.

A complete reply to the second part, "Why," of the question propounded for consideration has, by no means been given; but the first part of the question, we feel, has been conclusively answered: the effect of material upon tone quality of wind instruments certainly is not a fable.

DAYTON C. MILLER

CASE SCHOOL OF APPLIED SCIENCE

REPORT OF COMMITTEE ON STANDARDS OF AMERICAN UNIVERSITIES¹

THE Committee on Standards of American Universities begs leave to report as follows:

¹ Amended and adopted by the National Association of State Universities, Washington, D. C., November 17, 1908.

The committee originally was appointed at a session of this association in Washington, D. C., November 13, 1905, and consisted of Presidents Bryan, of Indiana, James, of Illinois, and MacLean, of Iowa, Chairman. The resolution under which the committee was appointed reads:

That a committee be appointed that shall report later to this body upon standards for the recognition of American universities and upon standards for the recognition of the A.B. degree and higher degrees.

The committee was unable to meet in 1905-6. The chairman presented a memorandum for a partial report at the session of the association, November 12-13, 1906, in Baton Rouge, La., and the committee was continued. At a meeting of the association in 1907, the committee asked for further time. The request was granted and at the special meeting of the association in Chicago in February, 1908, President Baker, of Colorado, was added to the committee. The committee has had several extended sittings and unites in the following statements and recommendations:

Your committee believes that there are certain clearly marked tendencies or forces at work in our American society toward a development, at no distant date, of a typical institution of learning, which we may not improperly call the Standard American University.

This institution will, for an indefinite time, include as an important part of its organization what we may call a Standard American College, with a four-year curriculum, with a tendency to differentiate its parts in such a way that the first two years shall be looked upon as a continuation of, and a supplement to, the work of secondary instruction, as given in the high school, while the last two years shall be shaped more and more distinctly in the direction of special, advanced or university instruction, rising gradually into the advanced work of the graduate school.

The Standard American University will also include as a distinct department the graduate school or philosophical faculty.

It will also include as organic parts of the institution in its fully developed form, vari-

ous professional schools such as law, medicine and engineering.

Present tendencies point, in our opinion then, to a definite differentiation in the work of the college at the close of the sophomore year toward university work in the real sense. If these views are just, we suggest the following formulation of principles underlying the organization of such an institution and we may define the Standard American University to be an institution: (1) Which requires for admission the completion of the curriculum of a standard American high school with a "four years" course, or in other terms, the completion of a course which will enable the pupils to offer not less than fourteen five-hour units, or equivalent; (2) which offers in the college of literature and science two years of general or liberal work completing or supplementing the work of the high school; (3) which offers a further course of two years so arranged that the student may begin work of university character leading to the bachelor's degree at the end and reaching forward to the continuation of this work in the graduate school or the professional school; (4) which offers professional courses, based upon the completion of two years of collegiate work, in law, or medicine or engineering; (5) which offers in the graduate school an adequate course leading to the degree of doctor of philosophy.

It is recommended that this association

The definitions of *standards* in terms of time are used as a matter of convenience, but there shall be due opportunity in individual cases to show equivalents. In the definitions of *units* for collegiate entrance requirements, it is recommended that those now current in the North Central Association of Colleges and Secondary Schools, the Association of Colleges and Preparatory Schools of the Middle States and Maryland, the New England Association of Colleges and Preparatory Schools, the Association of Colleges and Preparatory Schools of the Southern States, the College Entrance Examination Board, the New England College Entrance Certificate Board and the National Conference Committee of the Associations of Colleges and Preparatory Schools, and those formulated by associations of experts, and accepted by the above bodies, be recognized.

recognize any institution, in whole or in part, doing work of this grade as, in so far, doing work of university quality.

In recommending that university work begin with the junior year of the college and that the professional schools be based on the first two years of college, the report is in line with present tendencies. It is in accord with the growing belief that the work of the last two years of college should be organized into groups that aim at more definite results, and lead to greater efficiency. But this is only the first of many problems. We are facing questions of the time beyond the junior year for attaining the Ph.D. degree, of adjusting the scheme of counting the last two years toward both arts and professional degrees, of the place of the A.B. degree, of the age when the period of general education should end, and of a possible reorganization of elementary and secondary education. But these questions are not ready for solution and hardly belong to the work of the committee at the present time.

In accordance with the foregoing definition of the Standard American University, it is recommended that the following standards be set up:

1. *Time Requirement for the Bachelor's Degree.*—Not less than sixty year-hours, or twelve units, of collegiate work shall be required for the bachelor's degree.

2. *Qualifications of Teachers.*—It is expected that the teacher in the high school shall have the bachelor's degree, or show evidence of equivalent attainment, and it is recommended that he have the master's degree. As a rule, the professors of all ranks in the collegiate work shall have the degree of doctor of philosophy, or its equivalent. The professors giving instruction in graduate work are expected to show, in addition to the possession of a doctor's degree, or its equivalent, their scholastic ability by successful research and publication, and above all, they must have demonstrated that they have power as teachers to inspire the students with zeal for research. Indeed, it is understood that all the teachers should possess the power of imparting knowl-

edge and of character building. In addition, the professors in the professional schools should give evidence of doing investigative work and those in technical schools, evidence of the power of practical research.

3. Institutional Facilities.—(1) There should be adequate general and departmental libraries, with (a) sufficient number of duplicate books for purposes of undergraduate instruction, (b) where graduate work is offered, books, monographs and other material for purposes of research. (2) There should be modern laboratories³ and apparatus, with (a) sufficient supervision for undergraduate teaching, (b) where graduate work is offered, research laboratories.

4. Time Units for Degrees.—Institutions providing for advanced work shall require three years or nine five-hour units⁴ from the beginning of the junior year for the degree of master of arts, or five years or fifteen five-hour units for the degree of doctor of philosophy, and with work in residence.⁴

5. Scope of Curriculum.—To be a standard university an institution shall be equipped to

³In the use of the term *laboratories*, not only those for the material sciences with opportunity for proper field work are included, but also museums and proper laboratories for the historical sciences and philosophy.

⁴The unit in the high school is reckoned usually from a period of forty minutes, with twenty periods in a week. The units in the college or university are reckoned from a period of fifty or fifty-five minutes, with fifteen periods in a week, the differences in length of periods and in number of periods a week being due to the maturity or training of the student.

⁵The units shall not necessarily be schedule hours, but their equivalent, and shall include credit for research and thesis work. It is of course understood that from the beginning of the junior year, there is the adoption of a group system suggested by the honor schools in English universities, or the separate faculties in the German universities, and that the kind of instruction contemplates investigation—in short, science with power—as the purpose. It is the intent that the cultural atmosphere shall permeate the work of the student who begins specialization and that something of the spirit of discovery and the earnestness it brings shall affect the cultural temper.

give instruction leading to the degree of doctor of philosophy in at least five departments, according to the standard prescribed in this report, and shall have at least one university professional or technical school. The term *university professional* or *technical school* shall not be applied to any professional or technical school that does not require the two years' collegiate training for admission.

Your committee further recommends as follows:

Provision for Recognition of Other Institutions.—Provision shall be made whereby institutions other than state universities may be freely welcomed to adhere to the standards set up by this association.

Committee on Standards

1. There shall be a standing committee on standards of five members, of which the honorary vice-president of this association (the United States Commissioner of Education) shall be one. The committee on standards may invite into conference representatives of other educational organizations interested in formulating standards.⁵

2. When institutions within or without the association seek to adhere to the standards, said committee shall have the power to recommend to this association for recognition, institutions meeting these standards and may, after report to this association and its approval, issue certificates to institutions, to departments and even to individual instructors.

3. The committee may employ assistance upon the approval of the executive committee, the compensation for such assistance, together with necessary traveling expenses, to be paid from a fund created for the purpose, raised by apportionment among the members of this association in accordance with the sum expended by each institution for salaries.

4. The committee or their representative

⁵Committee is made up of the following members: President Jacob Gould Schurman, *chairman*, *ex-officio*; Dr. Elmer E. Brown, United States Commissioner of Education, *ex-officio*; President William Lowe Bryan, President James H. Baker, President Edmund J. James, President George E. MacLean, *secretary*.

may, when invited, visit an institution applying for recognition, the expense of such visitation to be borne by the institution concerned.

5. In making recommendations as to institutions, the committee on standards shall give great weight to the character of the curriculum, the efficiency of instruction, the scientific spirit, the standard for regular degrees, conservatism in granting honorary degrees, and the general tone of the institution.

6. This committee shall further be charged with the duty of correspondence with institutions and governments at home and abroad to gain proper recognition of graduates and students from these recognized institutions, departments and individuals.

7. The committee on standards shall report further upon standards and classification and shall cooperate as far as possible with a similar committee of the Association of American Universities.

Publication of Standards and List of Institutions.—This association shall publish the standards that have been adopted and, from time to time, the list of institutions adhering to them.

WILLIAM LOWE BRYAN,
JAMES H. BAKER,
EDMUND J. JAMES,
GEORGE E. MACLEAN, *Chairman,*
Committee

THE SEVENTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY

THE American Committee for the Seventh International Congress of Applied Chemistry, which meets in London, from May 27 to June 2, 1909, has been completed and a list of the members follows. The fee for membership for men at the approaching meeting is one pound and for women fifteen shillings. It is suggested that subscription for membership be sent to the chairman of the American committee or to chairmen of the sub-sections, and that five dollars be sent for men's memberships in order to cover the necessary expense for postage, etc., which has been and will be incurred. The chairman of the committee or

the chairmen of the sub-committees will undertake to forward subscriptions to the London committee, or members may send their checks to Mr. Thos. Tyrer, treasurer, 10 Cromwell Crescent, London, S. W., England. In the latter case it is requested that notice be sent to the chairman of the American committee. Titles of papers, together with abstracts, should be sent first to the chairman of the section to which the papers belong, and he will transmit them to the chairman of the American committee for entry and transmission to London.

H. W. WILEY

LIST OF MEMBERS FORMING THE AMERICAN COMMITTEE

Harvey W. Wiley, chairman, American Committee, Washington, D. C.

Members of the Advisory Committee of Honor

Dr. John J. Abel, president of the American Society of Biological Chemists, Johns Hopkins University, Baltimore, Md.

Mr. Edward G. Acheson, president of the American Electro-chemical Society, International Acheson Graphite Company, Niagara Falls, N. Y.

Dr. M. T. Bogert, president of the American Chemical Society, Columbia University, New York City.

Dr. C. F. Chandler, former president of the American Chemical Society, head of the chemical department of Columbia University, Columbia University, New York City.

Dr. Frank W. Clarke, former president of the American Chemical Society, and honorary member of the English Chemical Society, Geological Survey, Washington, D. C.

Dr. Wm. H. Nichols, chairman of the General Chemical Company, 25 Broad Street, New York City.

Dr. Ira Remsen, president of the Johns Hopkins University, former president of the American Chemical Society, Johns Hopkins University, Baltimore, Md.

Section 1. Analytical Chemistry

Chas. Baskerville, chairman, The College of the City of New York, New York City.

T. L. Briggs, 25 Broad Street, New York City.

Louis Munroe Dennis, Cornell University, Ithaca, N. Y.

Parker C. Mollhiney, 7 East 42d Street, New York City.

Henry P. Talbot, Massachusetts Institute of Technology, Boston, Mass.

Fletcher P. Veitch, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.

Percy H. Walker, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.

Section 2. Inorganic Chemistry

J. D. Pennock, chairman, The Solvay Process Company, Syracuse, N. Y.

A. S. Cushman, Office of Public Roads, U. S. Department of Agriculture, Washington, D. C.
 Clifford Richardson, Cortlandt Street Building, 32 Church Street, New York City.

Wm. D. Richardson, c/o Swift & Co., Chicago, Ill.

W. H. Walker, Massachusetts Institute of Technology, Boston, Mass.

Section 3. Metallurgy and Mining, Explosives

Division a. Metallurgy and Mining

John Hays Hammond, chairman, 71 Broadway, New York City.

F. P. Dewey, 415-416 Colorado Building, Washington, D. C.

H. O. Hofman, Massachusetts Institute of Technology, Boston, Mass.

N. W. Lord, Ohio State University, Columbus, Ohio.

J. W. Richards, Bethlehem, Pa.

R. H. Richards, Massachusetts Institute of Technology, Boston, Mass.

Albert Sauveur, Cambridge, Mass.

Thomas D. West, Sharpsville, Pa.

Division b. Explosives

Chas. E. Munroe, chairman, The George Washington University, Washington, D. C.

A. A. Breneman, 97 Water Street, New York City.

Arthur M. Comey, E. I. du Pont de Nemours Powder Co., Chester, Pa.

Clarence Hall, U. S. Testing Station, 40th and Butler Streets, Pittsburg, Pa.

G. W. Patterson, U. S. Smokeless Powder Factory, Indian Head, Md.

Section 4. Organic Chemistry and Allied Industries

Division a. Organic Chemistry

William McMurtrie, chairman, 480 Park Avenue, New York City.

F. D. Dodge, 69 Avenue A, Bayonne, N. J.

A. H. Gill, Massachusetts Institute of Technology, Boston, Mass.

W. S. Gray, 76 William Street, New York City.

Arthur Lachman, Petaluma, Cal.

A. H. Sabin, 432 Sanford Avenue, Flushing, N. Y.

Homer E. Sawyer, 42 Broadway, New York City.

Division b. Coloring Substances and their Uses

Bernhard C. Hesse, chairman, 90 William Street, New York City.

Herman A. Metz, Comptroller of the City of New York, New York City.

Hugo Schweitzer, 427 West 117th Street, New York City.

I. F. Stone, 100 William Street, New York City.

Louis I. Waldman, Box 162, Albany, N. Y.

Section 5. Industry and Chemistry of Sugar

Charles A. Browne, chairman, Mallery Building, 80 South Street, New York City.

A. Hugh Bryan, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.

David L. Davoll, c/o Guantanamo Sugar Co., Guantanamo, Cuba.

Hubert Edson, Guanica Centrale, Porto Rico.

Wm. D. Horne, Yonkers, N. Y.

Section 6. Starch Industry

Division a. Starch Industry

T. B. Wagner, chairman, Heyworth Building, Chicago, Ill.

Arno Behr, Pasadena, Cal.

Henry Carmichael, Columbia University, New York City.

George J. Jenks, Huron Milling Company, Harbor Beach, Mich.

George W. Rolfe, Institute of Technology, Boston, Mass.

Division b. Fermentation

Francis Wyatt, chairman, 402 West 23d Street, New York City.

Carl Glaser, 22 South Gay Street, Baltimore, Md.

Julius Liebmman, 109-111 East 15th Street, New York City.

Samuel C. Prescott, 739 Boylston Street, Boston, Mass.

A. J. Schedler, Pabst Brewing Co., Milwaukee, Wis.

Section 7. Agricultural Chemistry

C. G. Hopkins, chairman, University of Illinois, Urbana, Ill.

R. J. Davidson, Virginia Polytechnic Institute, Blacksburg, Va.

J. G. Lipman, New Jersey Agricultural College Experiment Station, New Brunswick, N. J.

F. T. Shutt, Dominion Experimental Farms, Ottawa, Can.

J. T. Willard, Kansas State Agricultural College, Manhattan, Kan.

Section 8. Hygiene, Medical and Pharmaceutical Chemistry, Bromatology

Division a. Hygiene and Medical Chemistry

Reid Hunt, chairman, Hygienic Laboratory, U. S. Public Health and Marine Hospital Service, Washington, D. C.

William J. Gies, 437 West 59th Street, New York City.

Walter S. Haines, Rush Medical College, The University of Chicago, Chicago, Ill.

M. E. Jaffa, University of California, Berkeley, Cal.

Walter Jones, Johns Hopkins University, Baltimore, Md.

John Marshall, University of Pennsylvania, Philadelphia, Pa.

Division b. Pharmaceutical Chemistry

Joseph P. Remington, chairman, 1832 Pine Street, Philadelphia, Pa.

Virgil Coblentz, Columbia University, New York City.

Edward Kremers, University of Wisconsin, Madison, Wis.

A. B. Lyons, 72 Brainard Street, Detroit, Mich.

Samuel P. Sadtler, N. E. Cor. Tenth and Chestnut Streets, Philadelphia, Pa.

Division c. Bromatology

W. D. Bigelow, chairman, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.

E. M. Chamot, Cornell University, Ithaca, N. Y.
Chas. F. Langworthy, Office of Experiment Stations, U. S. Department of Agriculture, Washington, D. C.

Graham Lusk, 11 East 74th Street, New York City.

W. W. Skinner, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C.

Section 9. Photographic Chemistry

L. H. Baekeland, chairman, Yonkers, N. Y.

L. H. Friedburg, The College of the City of New York, New York City.

Frank W. Lovejoy, Eastman Kodak Company, Rochester, N. Y.

Henry M. Reichenbach, Yonkers, N. Y.

Maximilian Toch, 320 Fifth Avenue, New York City.

Section 10. Electrical and Physical Chemistry

W. D. Bancroft, chairman, 7 East Avenue, Ithaca, N. Y.

Chas. A. Doremus, 55 West 53d Street, New York City.

Russell W. Moore, U. S. Customs Service, N. Y.
Wm. J. Schieffelin, 81 Fulton Street, New York City.

S. P. Sharples, 26 Broad Street, Boston, Mass.

David Wesson, 24 Broad Street, New York City.

DARWIN ANNIVERSARY COMMITTEE

CONTRIBUTIONS to the fund of the Darwin Anniversary Committee of the American Association for the Advancement of Science have been received from the following persons:

C. C. Adams, C. F. Adams, I. Adler, L. F. Allabach, E. P. Allis, Jr., W. B. Alwood, Oakes Ames, A. P. Anderson, J. C. Arthur, F. Baker, F. N. Balch, L. B. Bangs, L. F. Barker, G. H. Barton, H. H. A. Beach, W. J. Beal, A. G. Bell, R. Bell, W. F. Baller, F. G. Benedict, M. Benjamin, C. W.

Bennett, E. W. Berger, C. J. S. Bethune, A. B. Bickmore, M. A. Bigelow, E. A. Birge, E. Blackwelder, E. L. Blackshear, C. J. Blake, A. F. Blakeslee, A. M. Bleile, D. Bodize, H. E. Bolley, D. Bovaird, Jr., C. P. Bowditch, H. P. Bowditch, J. C. Branner, W. H. Brewer, N. Bridge, N. L. Britton, W. E. Britton, A. E. Brown, W. Browning, H. L. Bruner, G. J. Brush, O. Bryant, H. G. Bryant, H. C. Bumpus, L. Burbank, T. J. Burrill, A. W. Butler, M. A. Carleton, P. P. Calvert, W. B. Cannon, J. McK. Cattell, T. C. Chamberlin, T. M. Cheesman, C. M. Child, G. P. Clinton, T. D. A. Cockerell, G. E. Coghill, W. C. Coker, J. H. Comstock, O. F. Cook, L. C. Corbett, J. M. Coulter, W. T. Councilman, E. Cowles, C. F. Cox, R. J. Cram, C. W. Crampton, W. O. Crosby, W. Cross, H. Cushing, H. P. Cuahing, U. Dahlgren, E. S. Dana, C. B. Davenport, F. H. Davenport, B. M. Davis, J. J. Davis, A. Davison, P. M. Dawson, B. Dean, C. W. Dodge, R. E. Dodge, J. M. Dodson, W. R. Dodson, H. H. Donaldson, J. Douglas, G. A. Drew, E. K. Dunham, G. F. Eaton, R. G. Eccles, C. L. Edward, E. M. Ehrhorn, F. W. Ellis, A. W. Evans, H. L. Fairchild, G. W. Fitz, H. Fletcher, R. Fletcher, S. Flexner, J. M. Flint, H. Fox, P. Frazer, S. H. Gage, W. F. Ganong, F. A. Genth, Jr., W. Gibbs, G. K. Gilbert, T. Gill, H. A. Gossard, F. O. Grover, M. F. Guyer, A. Hague, W. Hague, W. H. Hale, R. W. Hall, W. Hallock, B. D. Halsted, W. S. Halsted, J. H. Hammond, H. A. Harding, C. W. Hargitt, R. A. Harper, N. MacL. Harris, R. G. Harrison, J. A. Hartwell, W. M. Hays, T. E. Hazen, L. Hektoen, Y. Henderson, F. H. Herrick, C. A. Herter, A. B. Hervey, J. S. Hine, W. H. Hobbs, S. J. Holmes, D. R. Hooker, G. S. Hopkins, T. Hough, E. O. Hovey, M. A. Howe, E. E. Howell, W. H. Howell, G. C. Huber, G. S. Isham, M. Jefferson, E. C. Jeffrey, H. S. Jennings, C. W. Johnson, H. P. Johnson, J. B. Johnston, L. R. Jones, E. O. Jordan, T. H. Kearney, A. F. A. King, E. A. Kirkpatrick, G. M. Kober, H. Kraemer, A. C. Lane, F. S. Lee, T. G. Lee, G. Lefevre, J. Leidy, P. A. Levene, F. Leverett, E. C. Levy, W. Libbey, F. R. Lillie, E. H. Lindley, E. Lindsey, J. U. Lloyd, H. C. Lomb, A. A. Low, S. Low, P. Lowell, G. Lusk, E. F. Lyford, B. S. Lyman, G. G. MacCurdy, R. MacDougall, J. J. R. Macleod, C. L. Marlatt, R. Matas, W. J. Matheson, A. G. Mayer, A. S. McCreath, E. M. McClintock, S. J. Meltzer, M. M. Metcalf, C. H. Merriam, C. S. Minot, E. S. Morse, H. F. Nachtrieb, A. Nelson, S. Newcomb, R. C. Ogden, A. E. Ortmann, H. Osborn, H. F. Osborn, H. L. Osborn, G. H. Parker, R. Pearl, C. H. Peck, R. A. F. Penrose, Jr., A. W. Peters,

G. H. Perkins, H. Phipps, J. J. Pierrepont, G. A. Borsol, G. Pinchot, J. F. Porter, F. H. Pratt, S. Pratt, H. S. Pritchett, F. W. Putnam, R. Rathbun, R. W. Raymond, J. Reighard, E. L. Rice, W. K. Rice, W. E. Ritter, M. A. Ryerson, W. Sanders, C. Schuchert, C. P. Sigerfoos, L. Stejneger, G. M. Sternberg, F. L. Stevens, H. E. Sumner, F. Smith, R. S. Tarr, E. W. Taylor, W. A. Taylor, R. J. Terry, R. Thaxter, E. L. Thorndike, E. D. Tillman, J. E. Todd, J. H. Todd, S. M. Tracy, N. Transeau, A. L. Treadwell, A. H. Tuttle, von Schrank, F. C. Waite, C. Walcott, H. E. Walter, R. H. Ward, H. B. Ward, H. L. Ward, E. F. Ward, H. J. Webber, W. H. Welch, W. M. Wheeler, I. C. White, C. O. Whitman, H. S. Williams, W. S. Williamson, H. V. Winchell, C. E. A. Winslow, C. E. Woodruff, A. F. Woods, R. M. Yerkes, C. Zeleny.

All subscriptions exceeding one dollar in amount have been individually acknowledged.

CHARLES B. DAVENPORT,
Secretary

THE COLUMBIA UNIVERSITY DARWIN LECTURES

A SERIES of lectures on "Charles Darwin and His Influence on Science," will be given at Columbia University on Friday afternoons, from February 12 to April 16, 1909, in 309 Havemeyer Hall, at 4:10 p.m., with the exception of the introductory lecture, which will be given at 11:10 a.m., on February 12, the one hundredth anniversary of Darwin's birth. The lectures, which are open to the public, are as follows:

February 12—"Darwin's Life and Work," by Henry Fairfield Osborn, Sc.D., LL.D.

February 19—"Terrestrial Evolution and Paleontology," by William Berryman Scott, Ph.D.

February 26—"Darwin's Influence on Zoology," by Thomas Hunt Morgan, Ph.D.

March 5—"Darwin in Relation to Anthropology," by Franz Boas, Ph.D.

March 12—"Darwin's Contribution to Psychology," by Edward Lee Thorndike, Ph.D.

March 19—"Darwin's Influence on Botany," by Daniel Trembly MacDougal, Ph.D.

March 26—"Darwinism and Modern Philosophy," by John Dewey, Ph.D., LL.D.

April 2 (date subject to change)—"Cosmic Evolution," by George Ellery Hale, Sc.D.

April 16—"Darwinism in Relation to the Evolution of Human Institutions," by Franklin Henry Giddings, Ph.D., LL.D.

SCIENTIFIC NOTES AND NEWS

DR. HENRY F. OSBORN has been elected president of the New York Zoological Society.

DEAN FRANK OLIN MARVIN, of the School of Engineering of the University of Kansas, was elected president of the Sigma Xi scientific society at the recent Baltimore meeting.

DR. S. A. FORBES has tendered his resignation as professor of zoology in the University of Illinois, which position he has held since 1884. The resignation is to take effect on September 1, 1909. He will remain as director of the State Laboratory of Natural History and state entomologist.

DR. CHARLES ROCKWELL LANMAN, professor of Sanscrit in Harvard University, has been elected a corresponding member of the Institute of France in the Académie des Inscriptions et Belles-Lettres.

DR. WILHELM WALDEYER, professor of anatomy at Berlin, has been elected a foreign member of the Stockholm Academy of Sciences.

THE University of Berne has conferred the honorary degree of Ph.D. upon the Rev. W. A. B. Coolidge, M.A., fellow of Magdalen College, Oxford, in recognition of his works on Swiss history and geography.

M. FREUNDLER has been elected general secretary of the Paris Chemical Society in succession to M. Béhal.

MR. STANLEY FIELD, nephew of Marshall Field, who founded the Field Museum of Natural History, Chicago, and in his will left a bequest of \$8,000,000 to the institution, has been elected president in succession to Mr. H. H. Higginbotham.

THE board of regents of the University of Kansas has appointed Professor H. P. Oady, of the department of chemistry, to be official weather observer to carry on the work begun by the late Dr. Snow forty years ago.

THE Carnegie Institution of Washington has made a grant of \$3,200 to Professor E. C. Case, of the University of Michigan, for the preparation of two monographs upon the Permian reptiles of North America. Four years ago a grant from the same source of \$1,800

was made, and as a result Professor Case published the monograph entitled, "Revision of the Pelycosauria of North America," which has been reviewed in this journal.

MR. TAFT left for Panama on January 25 on the cruiser *North Carolina*, accompanied by the following engineers: Frederick P. Stearns, Boston; John R. Freeman, Providence, R. I.; James Schuyler, Los Angeles; Isham Randolph, Chicago; Henry R. Allen, Chicago; A. P. Davis, Washington, D. C., and Allen Hazen, New York.

DR. ELLSWORTH HUNTINGTON, instructor in geography at Yale University, will leave New Haven on February 10 for an extended scientific trip in Palestine and Asia Minor.

MR. FRANK A. PERRET, who contributed an article on "Some Conditions affecting Volcanic Eruptions" to the issue of *SCIENCE* for August 28, 1908, is at present engaged in investigating the conditions of the Calabrian earthquake.

THE Research Club of the University of Michigan will celebrate the Darwin centennial on February 17. The president, Professor Wenley, of the department of philosophy, will give the eulogy; Professor Reighard, of the department of zoology, will speak on "Darwin's Contribution to Zoology"; Professor Case, of the department of geology, on "Darwin's Contribution to Geology"; Dr. De Leng-Hus, of the department of botany, on "Darwin's Contribution to Botany"; and Professor Pillsbury, of the department of philosophy, on "Darwin's Contribution to Psychology." Further, in conjunction with the Michigan Academy of Science and the Society of Sigma Xi, the club will hold a public commemoration meeting on April 2, when the address will be delivered by Professor Scott, of Princeton University.

In addition to lecturing at the Sorbonne, Paris, and at the University of Oxford, President Roosevelt has consented to give a lecture before the students and faculty of the University of Berlin in May, 1910.

DURING the meeting of the Association of American Universities recently held at Ithaca, President Charles R. Van Hise, of the Uni-

versity of Wisconsin, lectured before the Cornell Chapter of Sigma Xi on "The Conservation of our National Resources."

PROFESSOR T. A. JAGGAR, JR., lectured before the Society of Arts of the Massachusetts Institute of Technology on January 21 on "The Scientific Aspects of the Messina Earthquake."

DR. GEORGE H. SHULL, of the Station for Experimental Evolution, Cold Spring Harbor, gave an illustrated lecture in the Friday Evening Course of Clark College on January 15, on "Plant Breeding, Economic and Scientific."

MR. H. E. ASHLEY, assistant chemist in the Technologic Branch of the United States Geological Survey, read recently a paper before the Columbus Section of the American Chemical Society embodying his recent researches on colloids in clays.

ON Friday evening, January 15, Dr. W. R. Brooks, of Hobart College, delivered a lecture on "Other Worlds than Ours" before the Stanford Scientific Society. On February 5 Dr. Robert T. Morris, of New York City, is to lecture before the same society on "A Canoe Trip to Hudson Bay."

THE following tablet was recently placed in Barney Hall, of Denison University, in honor of C. L. Herrick, who for many years was professor of geology and natural history in this institution:

CLARENCE LUTHER HERRICK

1859

1904

FOUNDER OF THE
DENISON SCIENTIFIC ASSOCIATION
BULLETIN OF THE SCIENTIFIC
LABORATORIES
JOURNAL OF COMPARATIVE NEUROLOGY
A TRUE TEACHER

A COMMITTEE has been formed to erect a monument in honor of E. J. Marey, the eminent physiologist. Subscriptions may be sent to M. Carvallo, at the Institut Marey, Parc des Princes, Boulogne-sur-Seine.

BRIGADIER GENERAL WILLIAM PRICE CRAIGHILL, past president of the American Society of Civil Engineers, died at Charleston, W. Va., on January 18, at the age of seventy-five years.

DR. CHARLES DENISON, a specialist in the treatment of tuberculosis, died at his home in Denver, Col., on January 10.

MAXTON H. GUILBEAU, professor of zoology at the Louisiana State University, died on January 16, 1909. He was a graduate of the same institution, and had been in charge of the zoological department for several years. Since 1906, he had been director of the Gulf Biologic Station. Owing to heavy university work, he was unable to carry on as much research work as he was ambitious of doing. In summer work at Cornell, he investigated the froth production of the "Spittle Insects," on which he published a paper in the *American Naturalist* for December, 1908. At the time of his death, he had been engaged for several months investigating the parasites of *Plutella brassica*, confirming the results of French investigators as to the development of many insects from a single egg. Unfortunately this work was left in such a stage that it will be impossible to bring it together for publication.

SURGEON-GENERAL JOHN EDWARD TUSON, a retired officer of the Indian Medical Service, the author of numerous contributions to medical science, died at Eastbourne, on December 24, at the age of eighty years.

DR. R. ENGLÄNDER, professor of mechanical engineering in the Vienna Technical Institute, has died at the age of fifty-nine years.

THE death is announced of Dr. A. Grigorief, for twenty years secretary of the Imperial Russian Geographical Society.

THE Darwin anniversary addresses delivered on Darwin Day before the American Association for the Advancement of Science have all been assembled, and will be published at an early date by Messrs. Henry Holt & Company. The title of the volume will be "Fifty Years of Darwinism, Modern Aspects of Evolution and the Various Biological Sciences, Centennial Addresses in Honor of Charles Darwin before the American Association for the Advancement of Science, Baltimore, Friday, January 1, 1909."

AT a meeting of plant pathologists called at Baltimore, December 30, 1908, in connection

with the meeting of the American Association for the Advancement of Science, Professor A. D. Selby, of the Ohio Experiment Station, was elected temporary chairman, and Mr. Donald Reddick, temporary secretary. The temporary committee, appointed at Washington, on December 15, consisting of C. L. Shear, Donald Reddick and W. A. Orton, presented its report recommending that an organization of American plant pathologists be perfected. The report of the committee was accepted and temporary organization was effected by the unanimous election of the following officers: *President*, Dr. L. R. Jones, Vermont Agricultural Experiment Station; *Vice-president*, Professor A. D. Selby, Ohio Agricultural Experiment Station; *Secretary-treasurer*, Dr. C. L. Shear, U. S. Department of Agriculture; *Councilmen*, Professor J. B. S. Norton, Maryland Agricultural Experiment Station; Dr. B. M. Duggar, Cornell University Agricultural Experiment Station. The five officers elected form a council which is to consider and make recommendations in regard to all questions relating to the permanent organization, policy and affiliation of the society. The next meeting will be called at such time and place as may be decided by the council.

THE calendar of the botanical seminar of the University of Nebraska for the present year contains the titles of forty-six papers to be presented at twenty-two meetings to be held during the present academic year. Among the meetings is a Darwin Anniversary on February 12, of which the program is as follows:

Mr. Pool: "Pre-Darwinian Evolution."

Dr. Walker: "The Life of Darwin."

Professor Ward: "Darwin as a Zoologist."

Professor Barbour: "Darwin and the Geological Record."

Professor Bessey: "Darwin's Contributions to Botany."

Professor Wilcox: "Darwin's Contributions to Plant Physiology."

THE note in regard to the Winnipeg meeting of the British Association for the Advancement of Science printed in *SCIENCE* for January 15 should have read:

The Honorary Local Secretaries of the British Association for the Advancement of Science to be held in Winnipeg from August 25 to September 1 of this year, are C. N. Bell, Esq., W. Sanford Evans, Esq. (Mayor), Professor M. A. Parker, and Professor Swale Vincent. Enquiries and communications on matters connected with the meeting should be addressed: To the Local Secretaries, British Association for the Advancement of Science, University of Manitoba, Winnipeg, Man.

A CABLEGRAM has been received at the Harvard College Observatory from Kiel, stating that the eighth satellite of Jupiter was photographed at the Greenwich observatory on January 10^h. 551, G. M. T. in

R. A. 10^h 56^m 46^s.7

Dec. + 7° 40' 46"

Daily motion in R. A. - 1^m 0"

Daily motion in Dec. + 1'

The satellite is visible in a large telescope.

THE American Geographical Society has made a collection representing the finest grades of wall maps, atlases and other appliances used in teaching geography in European schools. The collection has been made in the expectation that it will be useful to teachers of the subject and to those who are preparing to teach it. A descriptive catalogue has been prepared and the collection will be exhibited at the house of this Society, 15 West 81st Street, New York, till February 27. Later it will be loaned in whole or in part, to normal and training schools and other educational centers throughout the country as long as there is a demand for it.

THE board of consulting chemists appointed by President Roosevelt to pass on pure food questions has announced a decision in regard to the use of benzoate of soda. The report is signed by President Ira Remson, of Johns Hopkins University, chairman; Russell H. Chittenden, director of the Sheffield Scientific School of Yale University; John H. Long, professor of chemistry, Medical School, Northwestern University, and C. H. Herter, professor of physiological chemistry, College of Physicians and Surgeons, New York. Dr.

Alonzo B. Taylor, professor of pathology of the University of California, is a member of the board, but he was absent in Europe during the experiments. The most important of the findings are:

First—Sodium benzoate in small doses (under 0.5 gram per day), mixed with the food, is without deleterious or poisonous action, and is not injurious to health.

Second—Sodium benzoate in large doses (up to 4 grams per day), mixed with the food, has not been found to exert any deleterious effect on the general health nor to act as a poison in the general acceptance of the term. In some directions there were slight modifications in certain physiological processes, the exact significance of which modifications is not known.

Third—The admixture of sodium benzoate with food in small or large doses has not been found injuriously to affect or impair the quality or nutritive value of such food.

THE application made to Congress by Senator Lodge for charters for the National Institute of Arts and Letters and for the Academy of Arts and Letters having led to inquiries regarding the organizations, a statement has been issued by the executive committee of the academy. This institution, according to the statement, was organized in 1904 by the National Institute of Arts and Letters, which, in turn, had been organized by the American Social Science Association in 1898, with a view to the advancement of art, music and literature. The membership of the institute is 250, including representatives from all sections of the country, while the membership of the academy is limited to fifty and is chosen from that of the institute. The first seven members, chosen by ballot, were William Dean Howells, Samuel L. Clemens, Edmund Clarence Stedman and John Hay, representing literature; Augustus Saint-Gaudens and John La Farge, representing art, and Edward MacDowell, representing music. The academy has recently effected a permanent organization and has elected this executive committee: *President*, William Dean Howells; *Chancellor*, William M. Sloane, and *Permanent Secretary*, R. U. Johnson. The officers of the institute are: *President*, William M.

Officers; Vice-presidents, Henry Van Dyke, John W. Alexander, Arthur Whiting, Brander Matthews, and Hamlin Garland; **Treasurer,** Hamilton W. Mabie, and **Secretary,** R. W. Johnson.

Dr. WALTER B. PILLSBURY, director of the psychological laboratory, University of Michigan, and non-resident lecturer in psychology, Columbia University, will give a course of eight lectures on "The Psychology of Reasoning," in Schermerhorn Hall, Columbia University, at 4:10 P.M., on the days and on the subjects which follow:

Tuesday, January 19—"Logic and Psychology."

Wednesday, January 20—"Belief."

Friday, January 22—"Meaning and the Concept."

Tuesday, January 26—"The Psychology of Judgment."

Wednesday, January 27—"Judgment and Language."

Friday, January 29—"Inference, the Syllogism."

Tuesday, February 2—"Universal and Particular Conclusions."

Wednesday, February 3—"Induction and Deduction, Analogy."

UNIVERSITY AND EDUCATIONAL NEWS

MR. JOHN D. ROCKEFELLER has made a further gift of a million dollars to the University of Chicago. His gifts to the university now amount to more than \$25,000,000.

At the last meeting of the Board of Directors of Bryn Mawr College a gift of \$100,000 was presented to the Board by the Alumnae Association of the College, the first installment of the sum of \$1,000,000 which the alumnae have undertaken to try to raise for the additional endowment of the college. The alumnae have made it a condition of their gift that the money shall be used for academic salaries and they have endowed the chair of mathematics with this first \$100,000 and stipulated that the money released by freeing the college from maintaining this professorship shall be used in raising the salary of each full professor in the college. Professor Charlotte Angas Scott has held since the opening of the college the chair of mathematics, which the alumnae have endowed.

THE legislative board of visitors of the University of Missouri in its report to the governor of the needs of the university, recommended that the legislature appropriate \$475,000 for new buildings. Of this amount, the board recommended that \$250,000 be spent for a fireproof library building, \$100,000 for a physics building, \$75,000 for a chemistry building and \$50,000 for a women's gymnasium.

At Central University, Danville, Kentucky, Young Memorial Hall was dedicated on Friday, January 8. The speakers for the occasion were Dr. Henry S. Pritchett, president of the Carnegie Foundation for the Advancement of Teaching, Dr. Willis G. Craig, of Chicago, and Dr. J. M. Blayney, who spoke on behalf of the trustees of the university. Young Hall is a well constructed building, one hundred and twenty-two by seventy-six feet, made of buff brick and trimmed in light sandstone. The first floor and a portion of the basement will be occupied by the department of physics under the direction of Professor Clarence McChayne Gordon, Ph.D. (Göttingen); the second floor will be devoted to the work in chemistry, with Friend E. Clark, Ph.D. (Johns Hopkins), in charge.

A FOURTH report upon The High School Course in Botany adopted by the College Entrance Examination Board as a basis for its examinations, giving the course in full with certain explanatory matter, has recently been printed by a committee of the Botanical Society of America. A copy thereof will be sent to any one especially interested in this matter upon application to the chairman of the committee, Professor W. F. Ganong, Smith College, Northampton, Mass.

THE newspapers state that President Benjamin Ide Wheeler, of the University of California, has declined the presidency of the University of Michigan.

DR. E. A. NOBLE will be installed as president of the Woman's College of Baltimore on February 2.

PROFESSOR GEORGE F. SWAIN, professor of civil engineering at the Massachusetts Insti-

tute of Technology, and Professor H. E. Clifford, professor of electrical engineering at the institute, have been elected professors at Harvard University, in the School of Applied Science established under the McKay bequest.

DR. ARTHUR WILLIAM MEYER, professor of anatomy in the Northwestern University, has been called to the chair of human anatomy in Stanford University.

HAROLD D. NEWTON, assistant in chemistry at Yale University, has been elected professor of chemistry at the State College at Storrs, Conn.

DISCUSSION AND CORRESPONDENCE

CONVOCATION WEEK

TO THE EDITOR OF SCIENCE: The leading editorial in your issue of January 8 contains much food for reflection. Those of us who were at the Baltimore meetings were offered a very unusual menu from which to choose according to our individual tastes and needs. Though one may sometimes have had to deviate from a normal ration, there is no reason why any one should have left the great meeting just closed with his hunger and thirst after knowledge unsatisfied.

Perhaps never before have there been so forcefully illustrated the advantages and disadvantages of a great program with multiple divisions and subdivisions, geographic segregation of the less loosely allied interests, and more or less effective contiguity of those more closely connected.

The purpose of this letter is to call attention to the loss experienced by a large part of the persons present of some of the choicest special "courses of the day." You enumerate interesting public lectures on several questions of broad scientific interest. Charged with the duty of attending executive sessions and the meetings of special sections and affiliating societies, I question whether a tithe of those participating in the great gathering knew of most of these opportunities until they had missed them. This resulted through no fault of officers, but through the common habit of men of looking first to the things that most immediately concern them—

and, finding so much of immediate concern, failing to look further.

Why can not the American Association provide best for such lectures by suspending all section sessions before eleven o'clock, and holding a general session of forty-five minutes' duration every morning at ten for the presentation of a masterly address? The possibilities of interesting people who are not specialists in the work of the association seems to me likely to be furthered more by such a daily broad-subject large-man address, protected from encroachment of the special sections, than by any other one step which is feasible. Evening engagements are always likely to interfere with such lectures, and the evenings are becoming more and more the property of the affiliating national societies.

Complaint is made of the multiplicity of subjects and papers offered the various sections and societies. There is little profit in quarreling with the increasing scientific activity of the country. It has come and we all want it to stay. In my own field, the secretaries in Section G and the Botanical Society of America cooperated so well that the joint program was found workable to an unusual degree; and the special Darwin and ecology sessions of the national society, devoted to papers prepared on invitation, contrasted with the more democratic sessions of the section in a way very suggestive of a good outcome from a general differentiation of society and section activities along these cleavage lines.

WM. TRELEASE

GRAY'S NEW MANUAL OF BOTANY¹

The writer of this note is not aware whether the authors have printed an unillustrated edition of their revised edition or not. Indeed, for the purpose of this criticism this would make little difference, that is, if the present illustrated copy is to be available for purchase by students. The writer may have a misconception of the value of Gray's "Manual," but takes this opportunity to allow that misconception to be made known, if it is to be classed as a misconception. He has

¹ By Robinson and Fernald, seventh edition, illustrated.

thought the great value of Gray's "Manual of Botany" as a guide for young students of the science has been that in the fewest words possible, and in the most exact manner those old manuals from year to year have always served as a guide for the young student to find the position of the plant in which he is interested in the plant kingdom. But in order to do this he has always had to work, except in the particular cases in which the common names were given. I note with a feeling of real regret and a feeling of real apprehension for the value of the "Manual" in training young students, that the authors have added pictures of many of the common species of plants. The best training in science that I have was given me through my personal efforts to identify plants in which I was interested. I feel, if at that time I had had Gray's "New Manual," seventh edition, illustrated, that much of any ability that I may now have along the line of noting fine distinctions in the structure of plants and details of variation, would never have been developed. There never was a time when I was not hunting for a shorter road, and had I had this well-illustrated "Manual" to look at I certainly should not have struggled up through the details of structure and wording. I could not have done so had I wished, for there would have been the pictures staring at me warning of a seeming waste of time. I could not have made errors which in the very making impressed the inefficiency of my work upon me. Though the drawings which the authors have given do not show the features and variations which the natural plant should bring to the student, yet they nevertheless show the general characters so plainly that when the pages open the student will have the name of his species lying immediately before him. My belief is that the value of the old "Manual," unillustrated, consisted essentially in the fact that it compelled the student to study out every detail of the plant before him in order to prevent the possibility of going astray in the divergent lines. Some one may say, now the work will be upon species and not upon genera and families. This must certainly be

the result, for there will be no possible way for a teacher to prevent the student from tracing his plant backward. In this it would appear that the author believed that the actual fact of knowing the name of the plant will be of more value to the student than the digging out of the detailed characters observed in the specimens, and comparing these with the fine gradations in the meaning of the words of the descriptions. What teacher of botany has not had difficulty in getting the average student to study the characters of the dandelion for the reason that the common name has always been appended? To illustrate my point, I think I am safe in saying that many fairly well-trained botanists would have difficulty in determining the position of the plant known as ball-mustard (*Neslia paniculata*) if they should chance to have parts of the fruiting stalks only for examination. Yet the high-school teacher will only need, now with the "New Manual," to turn the question over to the most simple-minded of his pupils and he will settle it within the space of a few minutes by the simple process of comparing the picture with the plant. I ask, will the pupil have any more knowledge of plants when through?

Teachers of botany in agricultural colleges have long contended that much of the old-line botany is a waste of time, but I believe the readers of this note will have hard work to find a botanist of any intelligence who will agree that the pictures add to Gray's "Manual" as a student's text or reference book, or will in any way tend towards the improvement in the thinking ability of high-school students.

It is much to be hoped that high school superintendents and high-school teachers will not have the desire to have their pupils learn how to work by an easy road of picture comparison, and will still continue to use unillustrated manuals that their pupils may not be deprived of one of the finest sources of botanical education. Plant anatomy and plant physiology may have been greatly aided by the development of well illustrated texts, and the studies may have been popularized somewhat thereby, but the writer can not be-

lieve but that the illustrations of species published in connection with the "Manual" will do away with most of the usefulness it may have had as a training subject preliminary to advanced studies upon plant life.

DISTRIBUTION OF THE NOBEL PRIZE

TO THE EDITOR OF SCIENCE: In his interesting and important address as retiring president of the American Association for the Advancement of Science, printed in your issue of January 1, Professor Nichols makes two statements regarding which I wish to submit a bit of confirmatory evidence, derived from the awards of the Nobel prizes for the eight years that they have been established.

The two statements are: (1) "The men who have laid the foundations upon which civilization is built have nearly all been teachers and professors." (2) "We have less than our share of men of science."

Each year five Nobel prizes of a value of about \$40,000 each are awarded, three of which alone, those in physics, in chemistry, and in physiology and medicine, concern us at present. These are awarded to the persons who have been most serviceable to mankind during the preceding year by making the most important discovery, invention or improvement in the designated field. The other two prizes are for work in literature and for work in the interest of international peace. Of the 24 prizes for scientific work of this description 16½ have been awarded to university professors, 3 more to directors of scientific research institutes, 3 more to teachers in scientific schools of high grade, viz., Royal Institution of London, École Polytechnique, and School of Physics and Industrial Chemistry of Paris (a divided prize) and the Academy of Military Medicine in St. Petersburg, and only 1½ to persons apparently not engaged in teaching. Even if allowance is made for one or two cases, like that of Major Ronald Ross, in which the scientific work was

done first and the position as a teacher resulted from it, it seems clear that at least four fifths of these prizes have been awarded to teachers in institutions designed to encourage research.

With reference to the second point quoted above it should be noticed that the Swedish committees of award have shown no tendency to favor Swedish or Scandinavian scientists. They have allotted the prizes to persons in the various countries as follows:

Germany	8	Sweden	1
England	5½	United States	1
France	4½	Italy	½
Denmark	1	Spain	½
Netherlands	1	Total	24
Russia	1		

Does not the above grouping correspond roughly to the order in which most scientists would arrange the great countries with reference to their important contributions to the advance of knowledge and support in an interesting way the second claim of Professor Nichols?

QUOTATIONS

HARVARD UNIVERSITY AND THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY

It seems probable that the taking from the institute by Harvard of two of its leading professors will bring up again the question of a consolidation or of an alliance between these two educational institutions. Recognizing the position occupied by the institute, President Eliot, of Harvard, throughout the whole of his long administration has refrained from developing technical education along extensive lines. His attitude in this respect is the more noticeable when the great development of the university in all other professional fields is considered, and it is also remarkable because during this period there has been great development in technical education in almost all other institutions, the students in technical subjects forming in many institutions by far the larger part of the undergraduate department.

Only to such subjects was special attention given as was demanded by specific gifts, mining, metallurgy and architecture being instances. The reason for this restraint was regard for the institute and the admirable work which it was doing and the belief that there should be but one technical school in Boston. President Eliot continually sought a merger with the institute and refrained from developing a competing school.

The McKay bequest to Harvard brought about a crisis and two years ago more active steps were taken to consolidate the institute with Harvard. It is related that once when the merger came up before the Harvard Faculty of Arts and Sciences a member of the faculty inquired what Harvard was to get out of it, to which President Eliot replied: "The merger is a subject under discussion by two groups of gentlemen, the Corporation of the Massachusetts Institute of Technology and the Corporation of Harvard University, and the sole consideration is the good of technical education in the community and in the country at large."

When the merger was abandoned Harvard still sought an organization which would compete in the least possible manner with the institute. The terms of the McKay bequest, however, made it necessary that Harvard give instruction in the same subjects as is given at the institute, and the university found its best solution of the situation in the organization of the Graduate School of Applied Science. Following its general motive of giving the best education to the exceptional student, Harvard has developed those subjects which are not touched upon by the institute, such as forestry and applied biology, the latter in the reorganized Bussey Institution, which has been made a part of the Graduate School of Applied Science. The McKay bequest now makes it necessary to develop the other branches, and in so doing to seek the best possible men. Two such men are considered Professor Swain and Professor Clifford.

The election of Professor A. Lawrence Lowell as president of Harvard, it is also thought, may have an influence in bringing Harvard and the institute into closer relation-

ship. President-elect Lowell is a member of the corporation of the institute and when the merger discussion was on he used his utmost efforts to bring about a union. As president of Harvard he will be in a better position to accomplish this object. Harvard will have ample funds for its School of Applied Science and can employ the best teachers there are. It also has sufficient land for the location of proper buildings. The institute, on the other hand, is handicapped by an improper location and insufficient funds to compete successfully against Harvard, fortified by the McKay bequest.—*Boston Transcript*.

SCIENTIFIC BOOKS

Mechanics of Engineering, comprising Statics and Kinetics of Solids; the Mechanics of the Materials of Construction, or Strength and Elasticity of Beams, Columns, Shafts, Arches, etc., and the Principles of Hydraulics and Pneumatics, with Applications. For use in Technical Schools. By IRVING P. CHURCH, Professor of Applied Mechanics and Hydraulics, College of Engineering, Cornell University. Revised edition. Pp. 854. New York, John Wiley & Sons. 1908.

Since the publication of Rankine and Weisbach, perhaps no single treatise which has attempted to cover the wide field of applied mechanics as taught in our American colleges of engineering, has been more useful than this one.

It has appeared in edition after edition until it would seem as if practically all the younger generation of engineers in this country must be familiar with it either as a text-book or as a work of reference. The book originally appeared in parts during the years 1886-7-8, so that it has now quite attained its majority. Its wide use by the profession has been due to its merits, which are many.

I may here mention some of them: 1. The subject matter of this book, which is central and essential to the training of every engineer, is presented as a series of semi-detached problems or developments which may be readily mastered separately, no one of which

requires ready familiarity with other parts of the book to make it available.

This kind of treatment may be likened to that used in the Euclidian geometry where a separate demonstration is invented for each proposition and few general methods are employed, a treatment in contrast with the developments of analytical geometry where general laws and methods are applied to successive cases or investigations. This kind of treatment has many advantages from the point of view of the practical man, while its disadvantages are perhaps principally encountered by those who must at some period of their career go somewhat more deeply into theoretical questions.

The contrast between the kinds of treatment I have in mind will be clear to any one who compares Grashof with Church.

2. The diagrams employed by Church were, I think, unique at the time his book was first published, in their combined simplicity and perspicacity. This arose, as I imagine, from the way in which the book came into existence as a transcript of the author's black-board lectures before his classes. Professor Church had the opportunity while yet a young man to devote himself to the single subject of applied mechanics exempt from the distractions which usually beset college teachers of that period of life who commonly have to teach first one and then another subject. He improved that opportunity to prepare this text-book. It was an excellent thing to do, and it was well done. It has stood the test of prolonged use. No important or extensive revision of the work has been undertaken by the author until now, and even now its general character and text has remained unchanged. To make a rough estimate, possibly 100 pages scattered throughout the book have been rewritten and replaced by a new or revised text, leaving the paging unchanged of so much of the original text as is retained. It is needless to say that the emendations and revisions have added greatly to the value of the book by the introduction of much new matter now necessary to the engineer, notably concrete beams, circular ribs and hoops, thick

hollow cylinders and spheres. The most important matters thus added are in the more abstruse parts of the subject, so that for the ordinary student the most important addition consists in the introduction of many valuable illustrative examples, a change which will meet general commendation. Indeed, the book would be improved by the introduction of still further examples. Another change, apparently small, but of real importance, is the adoption of 1.41 for the ratio of the two specific heats of gases instead of $4/3$ used in previous editions, following the example of Weisbach. While $4/3$ may be admissible as a rough average for gases whose molecules consist of three or more atoms, the gases the engineer ordinarily deals with consist so largely of diatomic molecules, especially air, that there is no excuse for using a value differing from the experimental value for air, unless the gas to be treated be known to be some polyatomic fluid, such as superheated steam, carbonic acid, ammonia or the like.

As a whole the book is singular for its clear, lucid treatment, wise selection of subjects and subordination of mathematical to mechanical considerations. It has more definitely in view the needs of the civil engineer than the mechanical or the electrical engineer. Indeed, the devotee of any of these branches of engineering must expect ultimately to specialize to a far greater extent than is possible in a general treatise like this.

HENRY T. EDDY

Allen's Commercial Organic Analysis. Third edition. Vol. II, Part III.

The volume in hand, which completes the treatise, is chiefly devoted to the aromatic substances and to the essential oils, resins, etc. The first part treats of the benzol derivatives included under the following heads: Characters and Classification of Aromatic Acids, Benzoic Acid and Its Derivatives, Cinnamic Acid and Its Derivatives, Salicylic Acid and Its Allies, Dihydroxybenzoic Acids and Their Allies, Gallic Acid and Its Allies, Phthalic Acids. Special attention is paid to salicylic acid, the detection and determination of which

is so important in relation to the pure food law. The various flavoring substances, such as vanillin, saccharin, etc., are treated at length, as are the medicinally important bodies throughout the book. The main portions of the volume, devoted to the essential oils, are, in the opinion of the reviewer, well written and up-to-date. The Extraction of Essential Oils, Classification, General Characters, Analysis, Constituents, Hydrocarbons, Olefinic Terpene Alcohols and Aldehydes, Cyclic Terpene Alcohols, Phenols and Phenolic Ethers, Ketones, Sulphuretted Constituents, Special Characters of Individual Essential Oils and Terpeneless Essential Oils are each discussed in a separate paragraph. The material given is quite full enough for practical purposes and no serious errors were detected. Especially useful are the tables of the important essential oils and of their constituents. Rubber and the resins are thoroughly discussed as follows: Caouchouc and Gutta-percha, Chemical Composition of Resins, General Character of Resins, Resins, Oleo-Resins or Turpentine, Gum-Resins. In general the volume is quite satisfactory.

ALFRED HOFFMAN

Las Plantas Usuales de Costa Rica. By HENRI PITTIER. Washington, H. L. & J. B. McQueen. 1908.

This work on the useful plants of Costa Rica will be welcomed by students of economic botany and tropical agriculture. Professor Pittier has already produced several works relating to tropical agriculture, contributions to the flora of Costa Rica, monographs of certain Central American genera of plants, and treatises on the ethnology and languages of several aboriginal tribes of Central and South America. The present work is illustrated with thirty-one plates, most of which are reproductions of natural size photographs of fruits and plants made by the author. An account of physical features and climate of Costa Rica is given, together with the characteristic plants of the various zones of vegetation, a list of plants grouped according to their uses, the etymology of their common names, derived as they are

from various sources, Nahuatl, or Aztec; the language of the ancient inhabitants of Hayti; various tribes of Central America; and even from the Quichua of the Andes of South America. In addition to these names those of Spanish origin are given. Then follows an alphabetical enumeration of the useful plants of the republic, a tabulated list of the number of species belonging to each plant family thus far known to occur within its limits, and an index to the plants under their botanical names. The work ends with a very complete bibliography of works on tropical agriculture and the botany of Central America. Professor Pittier's present work is the first of its kind dealing with Central America. It was published under the auspices and by the direction of the government of Costa Rica.

W. E. SAFFORD

Human Foods and their Nutritive Value. By HARRY SNYDER. New York, The Macmillan Co. 1908.

At last man is having his share of the results of science applied to animal life. The author clearly states the twentieth century view when he says:

It is believed that a better understanding of the subject of nutrition will suggest ways in which foods may be selected and utilized more intelligently, resulting not only in a pecuniary saving, but also in greater efficiency of physical and mental effort.

This volume will not only supply a need, but will satisfy a real want, a want becoming acutely felt by the laity who are asking for some comprehensible statements as to human foods and their various qualities and relative values. One feels instinctively the master dealing out knowledge at first hand. Here is no compiler sifting more or less ancient and possibly outgrown material.

Not only teachers and students but the business man who has been warned by his physician to take thought for his diet, the club woman who has to "write up a paper" will find sound science as well as useful information about the many kinds of human foods. Such passages as the two quoted below convey economic lessons of great importance.

In older agricultural regions, where the cost of beef production reaches the maximum, dairying is generally resorted to, as it yields larger financial returns, and as a result more cheese and less beef are used in the dietary. As the cost of meats is enhanced, dairy products, as cheese, naturally take their place (page 96).

Food notions have, in many instances, been the cause of banishing from the dietary wholesome and nutritious foods, of greatly increasing the cost of living, as well as of promulgating incorrect ideas in regard to foods, so that individuals and in some cases entire families have suffered from improper or insufficient food (page 253).

The tables showing composition, digestibility, etc., are taken from the publications of the U. S. Department of Agriculture, based on American work in which Professor Snyder has played a large part. The chapters on cereals and bread are mainly the results of studies in his own laboratory.

It would have added to the value of the volume as a text-book if some of the illustrations had been better prepared. A student would find some difficulty in recognizing the varieties of starch from the indistinct figures given. On page 90 the centrifuge should have been designated as of fractional size as compared with the other apparatus or have been omitted altogether.

The water analyst wishes there had been a word of caution on page 278 as to the metals of which cheap water stills are often made. The discussion of the ice supply might also have included the statement that all ice used directly in foods and drinks should be crystal clear and not frothy or bubbly.

The chapter on laboratory practise and the admirable review questions will prove most helpful not only to teachers of home economics but also to the general science teachers many of whom are just ready to use this kind of information in their classes.

ELLEN H. RICHARDS

SCIENTIFIC JOURNALS AND ARTICLES

THE opening (January) number of volume 10 of the *Transactions of the American Mathematical Society* contains the following papers:

Eduard Study: "Zur Differentialgeometrie der analytischen Curven."

G. A. Miller: "The central of a group."

J. I. Hutchinson: "The hypergeometric functions of N variables."

Virgil Snyder: "Surfaces derived from the cubic variety having nine double points in four dimensional space."

A. E. Young: "On a certain class of isothermic surfaces."

A. E. Landry: "A geometrical application of binary syzygies."

L. E. Dickson: "Definite forms in a finite field."

The December number (volume 15, number 3) of the *Bulletin of the American Mathematical Society* contains: "The September Meeting of the San Francisco Section," by W. A. Manning; "Note on Statistical Mechanics," by E. B. Wilson; "On certain Constants Analogous to Fourier's Constants," by C. N. Moore; "The Cologne Meeting of the Deutsche Mathematiker-Vereinigung," by R. G. D. Richardson; "Goursat's Cours d'Analyse," by W. F. Osgood; "Shorter Notices": D'Ocagne's Calcul graphique et Nomographie and Le Calcul simplifié, by L. I. Hewes; Durège's Theorie der elliptischen Funktionen, by J. I. Hutchinson; Vehlen and Lennes's Introduction to Infinitesimal Analysis, and Hedrick's Algebra for Secondary Schools, by James Pierpont; Sturm's Lehre von den geometrischen Verwandtschaften, Erster Band, and Scheibner's Beiträge zur Theorie der linearen Transformationen, by Virgil Snyder; Lebon's Table de Caractéristiques des Facteurs premiers, by G. A. Bliss; Serret-Scheffers's Lehrbuch der Differential- und Integralrechnung, by A. R. Crathorne; Blaschke's Mathematische Statistik, by H. L. Rietz; Fleming-Ashkinass's Elektrische Wellen-Telegraphie, by E. B. Wilson. "Notes"; "New Publications."

The January number of the *Bulletin* contains: "The October Meeting of the American Mathematical Society," by F. N. Cole; "On the Groups Generated by two Operators Satisfying the Condition $s_1 s_2 = s_2^{-1} s_1^{-1}$," by G. A. Miller; "The Teaching of Mechanics" (review of Jeans's Theoretical Mechanics), by E. W. Brown; "Economics" (review of

Fisher's Nature of Capital and Income and Rate of Interest), by E. B. Wilson; "Shorter Notices": Hesse-Gundelfinger's *Analytische Geometrie der geraden Linie, des Punktes und des Kreises in der Ebene*, by E. J. Wilczynski; Gray's Bibliography of the Works of Sir Isaac Newton and White's Scrapbook of Elementary Mathematics, by D. E. Smith; Royal Society Catalogue of Pure Mathematics, by G. A. Miller; Carslaw's Fourier's Series and Integrals, by J. E. Wright; Grimsch's *Angewandte Potentialtheorie in elementarer Behandlung*, by E. B. Wilson. "Notes"; "New Publications."

BOTANICAL NOTES

TWO RECENT PAPERS ON ALGAE

R. E. BUCHANAN's paper—"Notes on the Algae of Iowa"—in the *Proceedings of the Iowa Academy of Science*, Vol. XIV., opens with a historical account of the study of the Iowa algae, in which eight previous papers are noted extending over a period of twenty-eight years from 1880 to the present. The 181 species credited to the state are arranged mainly according to the system given in West's "British Freshwater Algae," and for each particular localities are given with the name of the collector, and often the date of the collection.

Of the *Myxophyceae* there are 45 species enumerated, of *Bacillariaceae* 5; *Heterokontae* 4; *Chlorophyceae* 127. No *Phaeophyceae*, nor *Rhodophyceae*, are known to occur in the state. This paper is to be considered as a preliminary report, for when the whole of the material collected by the author is worked over it is confidently predicted that many more species will be added to the algal flora of the state.

Somewhat like the foregoing is Conn and Webster's "Preliminary Report on the Algae of the Fresh Waters of Connecticut," published as Bulletin 10 of the State Geological and Natural History Survey. The authors say of it that "it is thought that it will be found to contain most of the common algae of the state." It, also, is based upon West's system, but no attempt is made to distinguish anything lower than the genera, the species

merely being enumerated, usually without localities being given. A somewhat hasty count of species gives for *Myxophyceae* 55 species; *Heterokontae*, 8; *Chlorophyceae*, 223; and *Rhodophyceae*, 10. Comparing these with the Iowa algae we find that the species of *Oscillatoria* are the same in number (9) in the two lists, that Iowa has 12 species of *Oedogonium*, to 2 in Connecticut: so of *Cladophora* the corresponding numbers are 7 for Iowa and 2 for Connecticut; *Vaucheria*, 7 and 3; *Zygnema*, 4 and 5; *Spirogyra*, 25 and 20. In these genera the preponderance is greatly in favor of Iowa, but when we take up the desmids (*Desmidiaceae*) it is quite the opposite, standing 26 for Iowa, to 109 for Connecticut. Forty-four well-drawn plates add greatly to the usefulness of the Connecticut report.

PAPERS ON FUNGI

THE quite extended paper (86 pages, and 9 plates) by George R. Lyman on "Culture Studies on Polymorphism of Hymenomycetes" (*Proc. Boston Society of Natural History*, vol. 23, No. 4, pp. 124-209) records the results of careful cultural studies, especially of woody and encrusting species. Besides the normal basidiospores formed by these fungi there are four others which may be regarded as secondary, viz., (a) chlamydospores; (b) oidia; (c) budding cells; (d) conidia. The author concludes that "a considerable majority of Hymenomycetes possess no secondary spores; that oidia are common among the *Agaricaceae* and *Polyporaceae*, and are confined to these two families; that chlamydospores occasionally occur in connection with the basidio-fructification, as in *Nyctalis*, *Ptychogaster*, and *Fistulina*, and are quite widely distributed on the mycelia of all families; and that conidia and other highly specialized secondary methods of reproduction are rare, and occur more frequently in the *Thelephoraceae* than in the higher families."

Professor Olive's paper on "Sexual Cell Fusions and Vegetative Nuclear Divisions in the Rusts" (*Ann. Bot.*, Vol. XXII., pp. 331-380) explains to a certain extent some of the discordant results of Blackman's and Christ-

man's earlier investigations. He concludes that the conjugations by means of which the cells of the rusts change from a uninucleated to a binucleated condition are not to be regarded as simple fusions for nutritive purposes as is common in many fungi, but as marking the beginning of the sporophyte generation.

In a paper entitled "Infection Experiments with *Erysiphe cichoracearum*" (Bull. Univ. Wis., Science Series, vol. 3, pp. 337-416) Dr. G. M. Reed takes up the question of "physiological species," and after making a great many infections concludes that his work "throws considerable doubt upon the existence of distinct biological forms" in mildews as well as in certain species of rust. The paper is so largely made up of tables that it can not be summarized.

C. H. Kauffman's "Unreported Michigan Fungi for 1907, with an Outline of the Gasteromycetes of the State" (in Tenth Ann. Report Mich. Academy of Science, pp. 63-84) adds many hitherto unreported species to the Michigan flora and includes a useful arrangement of the Gasteromycetes. The same author's paper on the Physiology of the Saprolegniaceae (in Ann. Bot., Vol. XXII., pp. 361-387) adds to our knowledge of the structure and development of these interesting fungi, and is especially valuable as suggesting methods of culture. The author modestly says that his paper "adds something more of evidence towards the doctrine that sex in plants is determinable by external conditions," distinctly disclaiming however that it is yet conclusive.

CONNECTICUT MOSSWORTS

UNDER the title "The Bryophytes of Connecticut" Professor Doctor Evans and Mr. G. E. Nichols publish (in *State Geol. and Nat. Survey, Bull.*, No. 11) an important contribution to our knowledge of the mosses and liverworts of that state. It opens with a well-written introductory chapter of 16 pages on the general structure of these plants, followed by a 5-page history of bryology in Connecticut (from which we learn that the first systematic work on these plants was undertaken by D. C. Eaton about half a century ago), half a dozen

pages of ecology, and two, on the economic values of bryophytes. Then follows the Catalogue of 387 species, distributed as follows: *Marchantiales*, 12; *Jungermanniales*, 92; *Anthocerotales*, 3; *Sphagnales*, 31; *Andreaeales*, 2; *Bryales*, 247. Under each species are given habitat, localities in the state, general distribution, exsiccata and references to descriptive or other papers. The bibliography includes 81 papers, beginning with Sullivant's "Anophytes" in the second edition of Gray's "Manual," in 1856, and coming down to the present. An excellent index closes this useful work.

CHARLES E. BESSEY

UNIVERSITY OF NEBRASKA

ANTHROPOLOGY AT THE BRITISH ASSOCIATION

THE Anthropological Section (H) of the British Association, held at Belfast last September, was notable for the number and excellence of the papers, many of which were fully illustrated with lantern slides. A précis of the proceedings will be found in *Nature*, but readers of SCIENCE may like to hear how America was represented. In his presidential address on "Totemism" Mr. A. C. Haddon criticized the terminology employed by most American students. He held a confusion had been made between totemism proper and the cult of a guardian spirit; doubtless American anthropologists will have something to say on this subject. Mr. W. J. Knowles, a local archeologist, described some stone axe factories that he had discovered near Cushendall in Co. Antrim, which recall in a small way, as was pointed out at the time, the bowlder quarries described by Dr. W. H. Holmes in the Fifteenth Annual Report of the Bureau of Ethnology. Mr. Knowles also exhibited some leaf-shaped flint objects which were probably an intermediate stage in the manufacture of arrow- and spear-heads and he alluded to the analogous leaf-shaped blades found by Mr. Holmes in the Piny branch quarry sites. Dr. W. H. Furness, third, of Philadelphia, read a very interesting and important paper on the "Ethnography of the Nagas of Eastern Assam," which was illustrated by a fine series

of colored photographs that often elicited applause from the audience. This paper will be printed in full in the *Journal of the Anthropological Institute*. Dr. Furness has traveled a great deal in the far east and his comparisons of the Nagas with the interior tribes of Borneo will prove of value—as he knows them all so well, as is proved by his recently published magnificent volume on “The Home-life of Borneo Head-hunters” (Lippincott Co.) and by the very valuable collection he has given to the Free Science and Art Museum of Philadelphia. Dr. Furness does not find a very close resemblance between the Nagas and Borneans which some have expected should occur. The Report of the Students Ethnological Survey of Canada Committee is practically nothing more than a memoir by Mr. C. Hill-Tout on the Mainland Halkomë’lem, a division of the Salish of British Columbia, but more especially with the Tcil’që’uk and Kwa’ntlen tribes of the Lower Fraser River. These ethnological studies run to over ninety pages, the greater number of which are devoted to linguistics. The Royal Society of Canada has at least awakened to the importance of recording the rapidly vanishing lore of the Canadian aborigines and it is to be hoped that some action will now result and that the Canadian government will assist in this important national work. The reading by Mr. J. L. Myres of a suggestive paper written by Dr. W. H. Holmes, entitled “The Classification and Arrangement of the Exhibits in an Anthropological Museum” led to a very interesting discussion in which Dr. W. E. Hoyle, Professor Boyd Dawkins, both of the Manchester Museum, Mr. H. Balfour, of the Pitt Rivers Museum, Oxford; Mr. G. Coffey, of the Royal Irish Academy Museum, Dublin; Mr. E. Lovett, and Dr. A. C. Haddon took part. Several speakers referred to characteristic features of American museums and pointed out some of the ways in which the English museums could be rendered more instructive and popular. It is beginning to be realized that a museum should be the educational center of a town, but in order to be that it must itself first be educational in its scope.

H.

SPECIAL ARTICLES

THE PRESENCE OF WATER VAPOR IN THE ATMOSPHERE OF MARS DEMONSTRATED BY QUANTITATIVE MEASUREMENTS

In 1867, Huggins first announced his detection of a slight intensification of the bands of aqueous absorption in the spectrum of Mars. The observation was an exceedingly delicate one, and resting, as it did, solely on eye-estimates of the relative intensities of weak lines which certainly do not differ very much in appearance, it is not remarkable that other observers, with even more powerful instruments, have declined to endorse the supposed intensification of aqueous bands, and have even denied its existence. Vogel, indeed, came to the aid of Huggins in 1873, and the opinion of two such accomplished observers was worth something. The question, however, up to the present time, has remained a matter of opinion only, with the honors about equally divided, the Lick observers declaring positively that no intensification was visible.

Under these circumstances, Professor Lowell's announcement that Mr. V. M. Slipher had succeeded in photographing the little α band in the spectrum of Mars under conditions which left no doubt of its relatively greater strength, may have passed with some as no more than a fresh subject for incredulity, and one to be relegated to the same limbo of “matter of opinion.” I therefore resolved to try to place these observations on a more solid basis, and with material aid from Professor Lowell, who has generously placed at my disposal the means for testing my ideas, I am now able not only to confirm Mr. Slipher's discovery, but to give numerical values for the amount of intensification of the α band. Besides this, it now becomes possible to give an approximate estimate of the amount of water vapor which is present in the air of Mars.

The instrument with which the examination of the spectrograms is made, I call a spectral band-comparator. It can be used for comparing the intensities of either lines or bands in two different spectra, but was more especially intended for the examination of

faint or diffuse bands in spectra of small dispersion, whence the name. After trial of other comparison objects, I conclude that nothing succeeds as well for the purpose of matching one of these hazy bands in a photograph of the spectrum as an equivalent, but not identical line or band in another spectrum of identical intensity as to the general background of continuous spectrum. The comparison line is chosen both narrower and brighter than the one to be measured in order that, when placed a little out of focus by a displacement of the objective of the microscope with which it is viewed, it may appear both broader and fainter, and may thus resemble the object with which it is to be compared. Beyond this, the observation consists simply in repeated settings of the microscope in its out-of-focus position corresponding to apparent equality of the hazy bands, and in the determination of a curve of brightness by a careful photometric calibration of the scale of the instrument.

The measurement is safeguarded in every possible way, and especially by duplicate measures, made on each one of the plates, of a line which is certainly solar and not subject to modification by the atmospheres of the planets. For this purpose the hydrogen *C* line has been made a test object, and also a means by which the measures on little *a* may be corrected for trifling variations in the focus of the spectrograph in the intervals between successive spectrum exposures.

The measures on great *C* in the spectra of Mars and the moon, taken at Flagstaff by Mr. Slipher at such times as to give equal altitudes for the two bodies at midexposure, and for such durations as to produce equivalent intensity of spectral background under identical photographic development, have a ratio which never departs much from unity; and the average ratio for all of the plates measured approaches unity much within the limit of the probable error. On the other hand, similar series of measures on little *a* show without exception that little *a* is more intense in the spectrum of Mars than in that of the moon, with equal *C* lines and for equal altitudes.

The average value of the direct readings of

the spectral band-comparator makes the intensity of *a* in the spectrum of Mars $= 1.224 \pm 0.0245$. The observations in full may be found in *Lowell Observatory Bulletin*, No. 86.

This result requires further correction by means of a calibration curve for the readings of the spectral band-comparator, before it can be stated in absolute units. To obtain such a curve, I have measured the disappearances of the same spectral line at various settings of the instrument with the modification of Pritchard's wedge-photometer invented by Dr. Charles H. Williams, of Boston, and called by him a "simplex" photometer. It is a well-known fact that the eye is much more sensitive to slight variations of intensity than we might have anticipated. But just as we do not recognize our faculty of discrimination, neither do we recognize how great the actual differences of intensities of illumination may be which correspond to our fallacious impressions of the same. Differences of illumination which we note immediately, but which are not judged to be great, which in fact, at first guess, we estimate as but a few per cent., turn out to be many hundred per cent. when made the subject of exact measurement. It is probable that very few would guess in the absence of exact measurement that a first-magnitude star is one hundred times as bright as a sixth magnitude. Bearing these facts in mind, it need excite no surprise when I state that the actual ratio of intensity of the *a* band in Mars, when expressed in absolute units, is much greater than would at first be inferred from the direct readings. I find that the real intensity of the band in the spectrum of Mars in the month of January, when the dew-point at Flagstaff was about 20° F., was *four and a half times as great as* in the lunar spectrum at the same altitude.

I have endeavored to find out how far it is possible for this result to have been vitiated by inequalities of photographic development. Some of the spectrograms of Mars have been over-exposed, but by a detail in the mode of procedure to which only incidental allusion has been made, namely, by altering the illumination of one or the other of the spectrograms

until identical illumination has been obtained, this diversity of photographic action, due to variation of exposure, or of development (of course with the proviso that such variations are never excessive), is apparently taken care of. At any rate, I find no difference in the results which can be traced to this cause.

Admitting that the little *a* band is four and one half times as intense in the spectrum of Mars, if we may assume that the intensity of the band is proportional to the total amount of vapor present in the combined air columns traversed by the rays, as it is very nearly in the case of incipient absorption, it is perhaps permissible to say, since the rays pass twice through the atmosphere of Mars, that on the average Mars has $0.5 \times (4.5 - 1.0) = 1.75$ times as much aqueous vapor in its atmosphere as that which exists above Flagstaff in the month of January, or roughly, since one and three quarters times the amount of water vapor in the surface air of Flagstaff would be 2.17 grains per cubic foot, or 5.0 grams per cubic meter, it may be concluded that the dew-point on Mars would be 33° F., if the distribution of moisture were the same in the upper air of the two planets. In this respect, however, there is a very wide divergence of conditions on the two worlds, since, as I have shown in my paper on "The Greenhouse Theory and Planetary Temperatures," in the *Philosophical Magazine* for September, 1908 (p. 469), the proportion of aqueous vapor existing at great elevations above the surface on Mars is very much greater than here. This is due to the comparatively rare atmosphere of Mars, to the low boiling point of water on that planet where water evaporates much more readily than here, and to the prevailing desert conditions, that is to say, to the infrequency of those atmospheric conditions which conduce to the formation of cloud and rain. Through these causes, aqueous vapor on Mars diffuses to greater heights and remains suspended in the air for longer intervals than with us. As a consequence, although there may be a very extensive protecting mantle of highly absorbent vapor which prevents surface radiation and conserves surface temperature, the dew-point

at the surface remains low, probably seldom rising much above the freezing point, and the prevalent conditions on Mars are those of a mild but desert climate, as Professor Lowell has all along maintained.

WESTWOOD ASTROPHYSICAL OBSERVATORY,
WESTWOOD, MASS.

THE SELACHIANS ADMITTED AS A DISTINCT CLASS

EVER since 1873 (*Am. Journ. Sci.* (3), 6, 434, 435) I have claimed class rank for the Selachians or Elasmobranchiates. This view has been later accepted by most American ichthyologists, and notably by Jordan, since 1902.¹ At last two European naturalists, of great eminence, have come to the same conclusion.

Professor A. A. W. Hubrecht, in the *Quarterly Journal of Microscopical Science* for November, 1908 (p. 156), has stated that "a division of the vertebrates in the superclasses of Cyclostomata, Chondrophora, and Osteophora might suggest itself, Amphioxus remaining yet more isolated in its superclass of Cephalochordata. The CHONDROPHORA would then contain the Elasmobranchs, the OSTEOPHORA all the other higher vertebrates."

Mr. C. Tate Regan, in the *Annals and Magazine of Natural History* for January, 1909 (8. ser., 3, 75), has recalled that he had "already expressed the opinion that the true Fishes are at least as distinct from the Selachians, on the one hand, and the Batrachians, on the other, as any of the vertebrate classes are from each other, and are equally entitled to rank as a class," and insists on their claim to class distinction.

Hubrecht and Regan, it is true, are not the first or only European naturalists to differentiate the Selachians as a class from the Pisces, for Geoffroy Saint-Hilaire and La-

¹ Up to 1887 Jordan had regarded the Selachians as a "class Elasmobranchii"; from 1888 to 1902 he associated them with the Pisces under two subclasses, Selachii and Holocephali; in 1902 he reverted to his former view. (See "Guide to the Study of Fishes," I., 1906, pp. 506, etc.)

² Regan, *Proc. Zool. Soc.*, 1906, p. 724, and "Biol. Centr.-Am.," Pisces, p. viii (1908).

treille did so nearly a century ago (in 1825), but almost all later Europeans have looked with much disfavor on such a separation. It must not be forgotten, either, that L. Agassiz, over half a century ago (in 1857), also separated the Selachians as a distinct class but, it should be said, he also differentiated the "Ganoïds" as an equally distinct class.* It is scarcely necessary to add that the reasons for the present differentiation of the Selachians are different from those influencing the early zoologists.

It may be hoped, in the interests of vertebrate morphology, that the view that has at last found favor among such active European naturalists as those noticed will be more prevalent than heretofore.

THEO. GILL

SEVENTH ANNUAL MEETING OF THE AMERICAN SOCIETY OF VERTEBRATE PALEONTOLOGISTS

THE seventh annual meeting was held in the geological laboratory of Johns Hopkins University, Baltimore, Md., December 28-30, 1908.

The meeting was called to order by President R. S. Lull on Monday, December 28, at 2:30 P.M. The minutes of the preceding meeting were read and approved. The treasurer's report was read and accepted. A letter from Professor W. B. Clarke was read, giving notice of courtesies extended to the society. A letter from the U. S. Fish Commission was read, acknowledging receipt of resolution regarding extinction of the great marine mammals, stating the sympathy of the commission with the views there expressed, and asking for suggestions in regard to prevention of this extermination.

The president appointed Messrs. Williston, Case and Matthew a committee to nominate officers for the ensuing year.

On motion it was resolved that the business meeting be postponed until 10:30 A.M. on Wednesday and that the meeting proceed to the reading of papers.

The reading of the presidential address by R. S. Lull, on "Dinosaur Societies," followed. The ad-

* Agassiz, "Cont. to Nat. Hist. U. S.," I., 1857, p. 187. Agassiz recognized three orders of Selachians ("Chimæra, Galeodes and Batides") and six (?) orders of Ganoïds ("three orders, *Cela-canths*, *Acipenseroids* and *Sauroids*; and doubtful, the *Siluroids*, *Plectognaths* and *Lophobranches*").

dress discussed the relationships and the geological and geographical distribution of the several groups of *Dinosauria* and suggested hypotheses of phylogeny and migration to explain these facts of distribution. (The address will be published elsewhere.)

Discussion: Dr. Williston expressed his sense of the importance and interest of the paper. He did not agree with the author in making the early Mesozoic migrations via a North Atlantic land bridge; a more probable alternative was by way of southern land connections. In favor of this view he pointed out our lack of knowledge of southern Mesozoic land faunæ, the easier communication at that time between the southern continents, and especially the presence of certain common types, such as *Dicynodonts*, in the early Mesozoic land faunæ of North America and Africa, although they are not found in the intervening northern land masses. He agreed with Professor Lull as to the Triassic age of *Nanosaurus*. In support of the lower Cretaceous age of a part of the Morrison formation he cited the discovery of *Morosaurus*, a Morrison genus, in the lower Cretaceous Trinity sandstone of Oklahoma. He believed that the American upper Cretaceous genera *Palæoscincus* (Judith River), *Stegopelta* (Lower Benton) and *Ankylosaurus* (Hell Creek) were closely related, if not identical, and were all derivable from *Polacanthus* of the Wealden of Europe. The recent discovery of *Ceratopsia* and of *Hadrosaurus* in the European Cretaceous reduces still further the supposed isolation of our late Cretaceous land fauna from that of Europe.

The meeting then adjourned. The second session was called to order at 9:30 A.M. Tuesday.

A specimen from the Conemaugh beds of West Virginia was submitted for discussion by Dr. White. The specimen appears to be the tibia or radius of a large reptile. Its nature and relationships were discussed especially by Drs. Williston, Case and Dean. It was considered to be beyond doubt a bone or natural cast of a bone of a large Pareiasaurian, exceeding in size and considerably older geologically than any known member of the order. On motion it was resolved that the society expresses its sense of the importance of the specimen and of the desirability of having it fully described and illustrated.

Dr. Williston then exhibited articulated skeletons of *Pariotichus* and *Lysorophus*, obtained for the University of Chicago in western Texas last summer. The reptiles of the American Permian included four chief groups, the *Pelycosaurs*, the *Cotylosaurs* (including *Chelydrosauria*) the *Pari-*

otichus group and one other. The *Pariotichus* group is ordinarily but not closely related to *Procolophon*. They were low, clumsy, crawling reptiles, large headed, with very primitive skull construction, pectoral girdle very primitive except for absence of cleithrum, 22-24 thoracic vertebrae, no intercentra, imperfectly double-headed ribs, some ventral armature, and very primitive, flat, plate-like pelvis. The phalangeal formula is not yet proved; there is no evidence as yet of the chelonian formula in any Permian reptile, and it is probably derived from the older formula with more numerous phalanges; the cervical vertebrae are short and few in number; the animal had practically no neck, as in the contemporary amphibians. The characters of *Lysorophus* have been stated in a recent publication by Dr. Williston; an important discovery is of evidence that it possessed completely formed limbs, although of small relative size.

Discussion: Dr. E. C. Case observed in regard to the abdominal ribs of the *Pariotichidae*, that they were present in certain specimens discovered by him last summer. The absence of intercentra was confirmed and its significance considered. The essential similarity, aside from a few highly specialized characters, of all these Permian forms as noted by Dr. Williston, is only explainable as a retention of primitive characters.

This paper was followed by "Notes on a Collecting Trip in the Permian of Texas, during the Summer of 1908," by Dr. E. C. Case. The author discussed the stratigraphy and conditions of deposition of the Texas red beds. No very satisfactory arrangement of these strata has yet been made. Professor Cummins's earlier arrangement was into (1) Wichita, (2) Clear Fork, (3) Double Mountain, successively overlying the Albany limestones, the Clear Fork being the chief fossiliferous horizon. The first two divisions are not clearly separable in Dr. Case's opinion. The succession in the part of the region studied by him was as follows:

(4) Conglomerate and sandstone layer similar to that below.

(3) Red clay, about 20 feet.

(2) Conglomerate layer, varying to a cross-bedded sandstone.

(1) Red clays.

The upper conglomerate forms the top of the country in the eastern part of the region. The sandstone is composed of molian sand, the conglomerate of rather angulate pebbles. West of Dundee the upper and lower conglomerate members come together and at the junction is a heavy

bone-bed. West of this comes in a new conglomerate layer. The strata were regarded as deposited along a lagoon-coast into which were washed the remains of animals and sediment from the dry land. They are not, strictly speaking, estuarine. Little is yet known of the geographic or geologic distribution of the fauna. The genus *Diplocaulus*, abundant north of the Wichita, has not been found south of it. Remains of insects—two well-preserved wings—were discovered by Dr. Case last summer, their first discovery in this fauna. Other interesting discoveries were a new reptile of small size and a new amphibian allied to *Zatrachys* or *Aspidosaurus*.

Discussion: Dr. Williston inquired whether the author considered that these beds indicated arid climatic conditions. Dr. Case: The beds themselves probably not, but the back country may have been arid; the bones occur chiefly in the conglomerate; in the clays they are very rare, but when found are apt to be articulated skeletons. This fauna was at least in part made up of dry land animals; the construction of the feet in *Dimetrodon* and *Naosaurus* is evidence for this view.

Dr. Gordon took some exception to the author's explanation of the stratigraphy, and discussed the relations of the sandstone layers. Dr. Williston observed that his experience last summer confirmed the general accuracy of Dr. Case's stratigraphy, but that river channels appeared to be more abundant; he illustrated a typical example which he had noted.

Dr. Gordon further discussed the paper, pointing out that the so-called Permian red beds of this region are in fact a northward continuation of the Albany limestone itself, instead of an overlying formation. This had been suspected by Dr. Cummins himself in the later years of his work.

Dr. David White discussed the relations of the plants of the formation and its geological age. In his opinion, it is probably Permian and not Carboniferous. The evidence of aridity did not seem very convincing. Dr. Gordon: As originally applied the Clear Fork and Double Mountain formations do really overlie the Albany. The mistake in Dr. Cummins's stratigraphy lay in his extending the Clear Fork eastward into Baylor County.

The president then called for the paper by Dr. Dean.

The author showed a series of micro-photographs illustrating the remarkable preservation of the muscular tissue in the fossil sharks of the

Cleveland shale, and remarked upon its rarity and interest. The striation of the muscular fiber could be clearly observed. In one specimen the form and structure of the kidneys of both sides were shown.

The next paper was by Dr. Matthew, on a skull of *Apternodus* and skeleton of a new Artiodactyl from the lower Oligocene of Wyoming. The specimens in question were obtained for the University of Wyoming by Mr. W. H. Reed, to whose courtesy and to the good offices of Dr. Williston the author owed the privilege of description. The *Apternodus* is an Insectivore of the rare and primitive Zalambdodont division; it is the third and most complete fossil skull referable to this group. The structure is peculiar in several respects, but its nearest relationships appear to be with the *Centetidae* of Madagascar. It affords some interesting data bearing upon the hypotheses regarding the origin of the tritubercular molar of mammalia. The second specimen represents a new stage of the Camel phylum, intermediate in most respects between *Protylopus* of the upper Eocene and *Paratylopus* and *Parbrotherium* of the middle Oligocene, but nearer to the former genus. The lateral digits of the fore feet are complete but slender; those of the hind feet are reduced to nodular rudiments. The proportions of the limbs, feet, skull and neck are as in *Protylopus*, lacking the elongate proportions of all the later camels; the tympanic bulla is of camelid type. The molar teeth are very short crowned and the upper molars peculiar in the development of a strong additional crest on the anterior wing of the posterior inner crescent. This crest is feebly developed in certain Giraffidae, not known in other artiodactyla. Except in this peculiar feature the new genus represents very satisfactorily the lower Oligocene stage in the evolution of the Camelidae.

The next paper was by Dr. Loomis upon the "Camels of the Lower Miocene." The author recognized two aberrant lines of camels, one represented by *Stenomylus*, the other by *Oxydactylus*, besides the more direct line of descent, imperfectly known at this stage of its evolution. A new species of *Stenomylus* was indicated by the series of complete skeletons found at the Amherst quarry, in which the premolars are further reduced than in the type of the genus. The author also showed drawings of a new species of peccary from this horizon.

The paper was discussed by Messrs. Cook, Matthew and Riggs.

Dr. E. S. Riggs then presented the results of his observations upon the Loup Fork beds of east-

ern Wyoming. The author had adopted in general the classification given by Mr. Hatcher. The Monroe Creek beds he had found hardly distinguishable from the Harrison and generally very barren. The Harrison beds are fossiliferous. The correlation between certain types of sediment and certain faunal groups of animals was noted. The strata were probably deposited by rivers in an open plains country. A list of the principal fossils was given, and the origin of the *Dæmonelix* beds was discussed at some length. The author had found remains of five different species of animals associated with the *Dæmonelix* spirals, viz., skulls and skeletons of *Stenocoelocyon*, skeletons of two genera of carnivora, a jaw of *Merychyon*, and parts of the skeleton of *Oxydactylus*. The last was partly without and partly within the spirals and the parts within had apparently been absorbed or eaten away. The other fossils lay completely within the spirals. Photographs of one of the carnivore skeletons were shown; the animal appeared to be coiled up in a natural position, as though resting upon a bed of sand within the cavity. It was concluded that at some stage of their formation these spirals had been open holes, but their mode of origin was still obscure. If they originated as burrows their formation must be ascribed to one only of the several animals found in them. In connection with a possible vegetable origin attention was drawn to the spirally coiled lianas common in tropical forests. These if buried in sand might decay and leave an open hole.

The paper was discussed by Messrs. Cook, Loomis and Matthew with regard to the correlation of the Harrison beds and the origin of *Dæmonelix*.

After which the meeting adjourned to 3:15 P.M.

The first paper of the afternoon session was by Dr. D. Matthew and Harold Cook, on a "Pliocene Fauna from Western Nebraska." The fossils described were from deposits lying just south of the divide between the Niobrara and North Platte Rivers in Sioux County, Nebraska, a new locality discovered by the authors last summer while prospecting in the interests of the American Museum of Natural History. The formation appeared to be a marginal phase of the Ogallala formation, and had been largely removed by eolian action, leaving in places only a residuum of gravels and coarser deposits of old channel beds, mantling the eroded surface of the Miocene beds. At other points the upper formation was more or less intact, and easily distinguished by the prevalence of true quartz sands and gravels of metamorphic and crystalline rocks. With the residual gravels of

the channel beds were great numbers of bones and teeth, mostly fragmentary and waterworn, but indicating a large and varied fauna. More than sixty species are represented by our collections, of which a considerable part are clearly new. Horses are the most abundant fossils, some hundreds of jaw-fragments and about ten thousand separate teeth being in the collection. All these belong to the Protohippine group, and are closely allied to those of the upper Miocene, but in some cases more specialized. *Equus* does not occur. A large variety of camels is present, some of gigantic size. The deer-antelope *Merycodus* is common, along with several kinds of true deer. The presence of true antelopes of the *Tragoceras* group is indicated by a horn, several upper jaws, teeth and skeleton bones. A single lower jaw is referable to the genus *Bison*, but its pertinence to this fauna is questioned. There are also several species of Oreodonts with a more advanced type of dentition than any described genera. Advanced species of the rhinoceros genera *Teleoceras* and *Aphelops* are present, and a Proboscidean of undetermined genus. The presence of Edentata is indicated by a single imperfect claw. Peccaries, several genera of rodents, and more than a dozen different Carnivora are represented. Most of them belong to known upper Miocene genera, but in several instances the species are more highly specialized. One lower jaw represents the modern genus *Bassariscus*, not heretofore known fossil. The age of the fauna is regarded as lower Pliocene, and the nearest comparisons are with the fauna of the Alachua clays of Florida and the Rattlesnake beds of Oregon.

In the underlying beds were found several skeletons of *Merychippus* and other genera, indicating that they are of middle Miocene age, equivalent to the Pawnee Creek beds of Colorado, and later than any of the Miocene beds in the Niobrara Valley to the north of them.

Discussion: Mr. Riggs observed that he had seen similar cases of residual deposits of bones in eastern Wyoming last summer.

Dr. Loomis remarked on the extraordinary abundance of animal remains gathered together within a small space at this locality.

Mr. Gidley observed upon the highly specialized character of the horses, which he thought compared most nearly with those of the Archer beds (Alachua clays).

Mr. Hussakof's paper then followed, "On a Method of Arranging Large Study Collections in Museums." The author described the methods of

arranging the fossil fish collections in the American Museum. They are placed in shallow trays in racks, an arrangement first introduced by Darwin. He advocated an arrangement primarily zoological, with a subordinate arrangement in alphabetic order. Special collections could be kept apart until studied and then merged in the general series. Space could be left for the addition of new material to the collections without disarranging the order. The paper was discussed by Mr. Gidley and Dr. Matthew.

The next paper was by E. B. Branson, "Notes on some Dinichthyids from northern Ohio." The author described a number of specimens of Dinichthyids recently collected for the museum of Oberlin College, including a fine skull of *D. intermedius* and a number of jaws and skull plates apparently of undescribed species. He also called attention to a specimen of Amphibian foot-prints from the Mauch Chunk shales of Pennsylvania.

Discussion: Dr. Hussakof inquired in regard to the occurrence of *D. intermedius* in the Delaware limestone as reported by Mr. Branson, and expressed some doubt as to the certainty of the horizon. He also noted the variable character of the mandible in the species of *Dinichthys*.

Mr. Branson, in reply, stated that there was no doubt as to the specimen in question being in place in the Delaware limestone.

The session was then adjourned.

On Wednesday, December 30, the society reconvened at 10 A.M. and proceeded with the program of papers.

Professor Osborn explained the plans of the International Committee on Geologic Correlation of the National Academy of Sciences. Professor Williston expressed his sense of the importance and desirability of the work as outlined. Dr. Loomis pointed out the need for field sections in the collecting of fossil vertebrates.

Professor Osborn then gave a preliminary report upon the skeleton of *Trachodon* discovered by Mr. Sternberg last summer. The specimen is articulated and complete except for the tail and hind feet. Careful preparation at the American Museum indicates that almost the whole integument is preserved, and the author described its character and pattern. The specimen was probably naturally mummified, and then buried by a mass of sand from a freshet. This skeleton, aside from its extraordinary interest in the preservation of the integument, will add considerably to our knowledge of the osteology of *Trachodon*, especially as regards the shoulder-girdle and its relations to the sternum and ribs. The paper was

illustrated by several slides, showing the locality and stages in the excavation of the specimen.

Professor Osborn then gave a brief description of the Cretaceous section in Montana in which the skeleton of *Tyrannosaurus* was found last summer, pointing out the sharp faunal distinction between the true Cretaceous and the Eocene part of the section.

Discussion: Professor Lull inquired whether this specimen throws any further light upon the supposed aquatic habits of *Trachodon*.

Professor Osborn replied that in general the view that these animals were waders rather than truly aquatic, appeared to be the most probable.

Dr. Williston inquired as to whether any carbon was preserved in the skin, as it is in so many instances in the Kansas chalk. He also recalled that in the excavation of the type specimen of *Morosaurus grandis* in 1878, considerable parts of the skin were found to be present in the form of a rather thick carbonaceous sheet. Owing to the unfavorable conditions, it was not then possible to preserve any part of the skin. He pointed out additional reasons against believing that the Dinosaurs were aquatic animals.

The problem of the habitat of the Sauropodous Dinosaurs was further discussed by Dr. Matthew, Dr. Williston, Mr. Riggs, Professor Lull and Mr. Gidley. Dr. Williston and Mr. Riggs advocated a terrestrial, Dr. Matthew and Mr. Gidley a wading, habit for this group.

In absence of Professor Osborn, Dr. Matthew then reported briefly upon the *Bison latifrons* skull recently acquired by the American Museum. This is believed to be the finest fossil bison skull on record. It measures nearly six feet from tip to tip of the horn-caves; the skull is but slightly larger than that of *B. americanus*, but shows several differences in form. It was discovered some years ago near Hoxie, in northwestern Kansas.

Discussion: Dr. Case mentioned a fine fossil bison skull in the collection of Iowa University. Dr. Williston observed that there was a very fine skull in the Leland Stanford University collections. It had not, he believed, been mentioned in print. He further discussed the characters of the different species of *Bison* and the geological horizon of *B. alleni*, reported by Marsh as Pliocene but probably Pleistocene. The living species *B. americanus* is also found in the late Pleistocene.

The program of papers being completed, the business meeting of the society followed.

The nominating committee reported that they

had agreed upon the names of Dr. J. C. Merriam for president and Mr. E. S. Riggs for secretary and treasurer. These nominations were accepted by the society and Messrs. J. W. Gidley, Barnum Brown and F. B. Loomis were then nominated as executive committee, and there being no further nominations, the secretary was instructed to cast a ballot for the nominees, and they were duly elected.

It was further resolved that the secretary with an assistant from the executive committee should have charge of the arrangement of program for the ensuing meetings, to avoid conflict with the programs of related societies whose meetings the members might wish to attend.

The following gentlemen were then proposed for membership: Professor E. R. Branson, Oberlin College, Ohio; Dr. Roy L. Moodie, Kansas University; Mr. W. H. Reed, University of Wyoming; Mr. C. H. Sternberg, Lawrence, Kansas; Professor C. E. McClung, Kansas University. After each name had been individually balloted upon, the president declared the unanimous election of all to membership in the society.

On motion of Dr. Loomis the following resolution was passed:

Resolved, That the American Society of Vertebrate Paleontologists, having found the "Bibliography and Catalogue of Fossil Vertebrates of North America," issued as a bulletin of the U. S. Geological Survey, of the greatest service in expediting research, do hereby request the director of the survey to prepare and publish a supplement to the same, to include the bibliography from 1900 to 1910, and do respectfully tender all assistance possible.

It was then resolved that the society express its appreciation and thanks to Professor Clarke and the Johns Hopkins University for their courtesies and efforts which had done so much to promote the success of the Baltimore meeting.

After which the society adjourned.

W. D. MATTHEW,
Secretary

SOCIETIES AND ACADEMIES

THE GEOLOGICAL SOCIETY OF WASHINGTON

At the 209th meeting of the society, held at the Cosmos Club, on Wednesday evening, November 11, 1908, Mr. Willis T. Lee spoke informally on an occurrence of coal changed to coke and graphite in the Raton, New Mexico, coal field.

During some period of volcanic activity after the coal beds had been formed igneous rock was

intruded into the beds. In some places this took the form of dikes, such as the "stone wall" at Raton; in other places it formed intrusive sheets thrust in between the beds. Where a comparatively small amount of this melted rock came in contact with the coal it changed the coal to coke, but where a large amount was injected the greater heat transformed the coal into graphite. This transformation was effected over an area of several hundred acres in Red River Valley.

Regular Program

Results of a Geodetic Study of the San Francisco Earthquake: Mr. JOHN F. HAYFORD.

The report of the California State Earthquake Investigation Commission is now being published by the Carnegie Institution. It includes a paper prepared by Messrs. Hayford and Baldwin, of the Coast and Geodetic Survey, giving the permanent displacements detected at sixty-one old triangulation stations, by new triangulation after the earthquake.

The permanent displacements to the northward on the west side and to the southward on the east side of the fault are greatest at the fault, and are nearly or quite parallel to it. On either side of the fault the permanent displacements decrease with increase of distance from the fault in such a way that lines on the surface of the ground and at right angles to the fault, which were straight before the earthquake, became curved lines after the earthquake, concave to the southward east of the fault and concave to the northward west of the fault.

At corresponding distances from the fault, especially near it, the displacements on the western side of the fault are twice as great, on an average, as those on the eastern side.

Mr. Hayford presented some considerations which lead him to believe that in such an earthquake the fault along which the displacements take place should not be expected to lie in the middle of the area which was under stress before the earthquake and the displacements should not be expected to be equal on the two sides of the fault.

Ordovician Paleogeography: Mr. E. O. ULRICH.

Mr. Ulrich exhibited paleogeographic maps of North America showing four stages of the Mohawkian epoch. Their explanation was preceded by a brief discussion of the classes of evidence available in paleogeographic studies. Roughly divided the facts bearing more or less directly upon paleogeography comprise two main classes:

(1) organic (composition and distribution of faunas and floras) and (2) physical (phenomena of stratigraphic overlap, character and distribution, with respect to known lands and seas, of the various kinds of deposits, marine and non-marine).

The presence and direction of ancient marine currents is determined primarily by organic criteria, but in a few cases their evidence is materially corroborated by facts falling under the physical class. It was pointed out, on the other hand, that the physical criteria of stratigraphic overlaps are but rarely sufficiently conclusive by themselves. As a rule they require the corroborative evidence of organisms before the overlaps may be accepted as established. In many cases also the overlap was originally suggested by purely paleontologic evidence, the physical evidence being so obscure that it is easily overlooked.

Further, it was pointed out that the physical criteria indicating coasts, especially of Paleozoic lands, are often exceedingly inconspicuous. Indubitable instances were cited of near-shore sedimentation, in seas submerging old lands, the true significance of which might perhaps never have been recognized if the beds had been unfossiliferous.

The first step in the preparation of paleogeographic maps is the solution of approximately synchronous facts. These must be primarily only organic. With such parts as a basis and check we may use orogenic movements which resulted in the emergences or submergences of large epicontinental areas. These movements are chronicled by the rocks and fossils, but it is the paleontologist alone who is responsible for their chronologic classification. Indeed, the determination of the relative age of geologic phenomena, hence the solutions of facts that may be reasonably assumed to be approximately synchronous, is the paleontologist's principal excuse for being. Considering his long training he may justly claim to have become an expert in such solution; and it is an undeserved reflection on his intelligence and attainments when a non-paleontologist says that a "New York formation can not be narrowly correlated with an equivalent in the Mississippi Valley," and that "the data of paleogeography do not admit of refined definition."

In the speaker's estimation the relative competency of the two classes of evidence, organic and physical, is, respectively, as four is to one; and that the latter without the support of highly

refined paleontologic data is as a ship devoid of rudder and skipper. It was further asserted that the "autocratic dicta" of the successful stratigraphic paleontologist of to-day are not based solely on comparisons of lists and collections of fossils but upon every physical fact that may have a bearing on the variation, horizontal and vertical, of faunas and floras. Obviously then, only an up to date paleontologist is equipped to produce a good paleogeographic map.

RALPH ARNOLD,
Secretary

THE SOCIETY FOR EXPERIMENTAL BIOLOGY AND
MEDICINE

THE thirty-first meeting of the society was held at the Rockefeller Institute for Medical Research, December 16, 1908, with President Lee in the chair.

Members present: Atkinson, Auer, Beebe, Burton-Opitz, Calkins, Carrel, Clowes, Elsberg, Emerson, Ewing, Famulener, Foster, Gies, Halsted, Hatcher, Jacobs, Janeway, Joseph, Kast, Lee, Levene, Levin, Lewis, Lusk, Meltzer, Meyer, Morgan, Noguchi, Opie, Pearce, Sherman, Terry, Torrey, Van Slyke, Wadsworth, Weil, Wood.

Members elected: Albert C. Crawford, W. H. Schultz and Thomas A. Storey.

Scientific Program

John C. Hemmeter (by invitation): Reply and explanation to recent criticism of Dr. Hemmeter's experimental study on effects of extirpation of the salivary glands upon the gastric secretion.

G. H. A. Clowes: A critical study of the conditions under which zymase and its associated co-enzyme bring about alcoholic fermentation.

Alexis Carrel: Presentation of a dog ten months after double nephrectomy and replantation of one kidney.

Don R. Joseph and S. J. Meltzer: A demonstration of the life-saving action of eserine in poisoning by magnesium.

A. O. Shalkee and S. J. Meltzer: The mechanical destruction of pepsin.

John Auer: A demonstration of the effects of CO₂ upon the frog's pupil.

¹ Authors' abstracts of the papers read before the Society for Experimental Biology and Medicine are published in the *Proceedings of the Society for Experimental Biology and Medicine*. A number is issued shortly after each meeting, and costs twenty cents a copy. Copies may be obtained from the managing editor, William J. Gies, 437 West 59th Street, New York.

Richard Weil: On the specific acquired resistance of red blood cells.

Hideyo Noguchi: The butyric acid reaction for syphilis in man and in the monkey.

D. D. Van Slyke and P. A. Levene: The quantitative separation of leucin from valin.

W. A. Jacobs and P. A. Levene: Further studies on the constitution of inosinic acid.

Ralph S. Lillie: The significance of changes in the permeability of the plasma membrane of the living cell in the processes of stimulation and contraction.

F. C. Becht and J. R. Greer (by invitation): On the relative concentration of lysins, precipitins, agglutinins, opsonins and related substances in the different body fluids of normal and immune animals.

Nellis B. Foster: Studies of the influence of various dietary conditions on physiological resistance. I. The influence of different proportions of protein in the food on resistance to the toxicity of ricin and on recuperation from hemorrhage.

Secretary

THE AMERICAN CHEMICAL SOCIETY
NEW YORK SECTION

THE fourth regular meeting of the session of 1908-9 was held at the Chemists' Club on January 8.

Mr. Frank Gottsch presented "A Simple Specific Gravity Apparatus for Portland Cement." His method, which he illustrated by a determination on the lecture table, depends upon the weight of cement required to replace a measured volume of kerosene removed from a graduated flask. It is rapid and gives results sufficiently accurate for commercial work.

The rest of the evening was devoted to the general subject: "The United States Patent Law: Its Use and Abuse." The speakers and their titles were:

F. I. Allen: "Introduction: Historical and Descriptive."

W. Hastings Swenarton: "Patents, Trade Secrets and Trade Names as Factors in Industrial Development—Their Relative Functions."

L. C. Raeger: "Some Defects in the Practice of Our Patent System and Suggested Remedies."

B. C. Hesse: "Some Suggestions as to Desirable Improvements."

L. H. Baekeland: "The Inventor's Standpoint."

C. M. JORDON,
Secretary

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE THE STUDY OF IGNEOUS ROCKS¹

No branch of petrology presents so attractive a field for investigation and study as that concerned with the origin and formation of igneous rocks. The great problems of metamorphism that traverse so much of the earth's dynamic history and involve so many factors common to the problems of igneous rocks are less alluring because of their greater complexity, and less definite character. While much is being done in each of these fields of rock study, it is to the former that I wish to call attention at this time. It is interesting to note how the attitude of the petrographer toward the subject of igneous rocks has changed with increasing knowledge of their composition, and with advancing experience with the fundamental laws of physics and chemistry.

Rocks that were considered igneous a century ago were almost wholly those known to have poured forth from volcanic craters, and were, for the most part, compact, aphanitic lavas, often containing porphyritic crystals—distinctly volcanic rocks. The great number of phanocrystalline massive rocks were not generally considered as having the same character and origin as volcanic rocks, as being igneous. Their formation was explained in different ways by various geologists. And when treated

¹ Address of the vice-president and chairman of Section E—Geology and Geography—American Association for the Advancement of Science, Baltimore, 1908.

as "plutonic," were still thought of as different from "volcanic" rocks. Some of the commonest were considered as extreme forms of metamorphism, and have been so treated until quite recent times by eminent geologists.

Not only the geological mode of occurrence of many of these rocks was unknown, or only partially known, but the inherent, material characters were often matters of conjecture. Before the introduction of the microscope by Sorby, in 1850, the mineralogical study was confined to the larger, megascopic crystals, except for the microscopical investigation of rock fragments and powder by Cordier in the first decade of the last century. And the early chemical analysis of rocks, while adding considerably to a knowledge of their composition as a whole, lacked the completeness and accuracy of modern analytical methods, and failed to explain the composition of the rocks because of the absence of satisfactory knowledge of the mineral components.

With improved methods of investigation, geological, mineralogical and chemical, knowledge of the character and composition of rocks advanced. The supposed distinction between "volcanic" and "plutonic" broke down, or assumed new definition, through the observations and writings of Judd and others. The term "igneous rocks" came into more general use, and embraced all "volcanic" and "plutonic" masses. The mineral composition of all crystallized igneous rocks became known in more and more exact terms, though much remains at present to be learned of the definite chemical composition of some of the common mineral components of most rocks. Chemical analyses of rocks are becoming more complete, and more frequent in petrographical publications, and the store of chemical data is steadily increasing and has been made more available by the collec-

tions of rock analyses published by Roth and more recently by Washington.

The description of igneous rocks has been largely fortuitous. As rocks happen to have been encountered in geological field work, they were collected, and not always with due regard to their geological relations to other rock bodies; and subsequently they were investigated in the laboratory, more or less thoroughly, and described, often very imperfectly. Up to recent times the terms "petrography" and "petrographer" applied satisfactorily to the subject and to the worker in it, for the work was chiefly descriptive.

Generalizations regarding the nature of igneous rocks, or the formulation of laws controlling their crystallization, were largely empirical dicta not infrequently based on incomplete knowledge or inadequate experience. As a natural consequence of the haphazard manner of growth of the science, there has been an unsystematic nomenclature, derived from many sources at widely remote times, expressing markedly different degrees of information regarding the thing described—rock, texture or relationship—and in many instances representing in a single term a series of definitions varying with shifting opinion or advancing knowledge. Such, for example, as syenite, granite and trachyte.

At the present time attempts are being made to apply to the study of igneous rocks the results of laboratory experience in physical chemistry and, not only to investigate directly the physical behavior of molten rock minerals singly and in combinations, or mixtures, but to apply the more advanced laws of physicochemical reactions to the elucidation of the problems of crystallization, differentiation and mineral composition. The researches of Day and his colleagues in the geophysical laboratory of the Carnegie Institution of Washington, D. C., upon temperatures of

fusion, crystallization, and transformation points of silicate compounds corresponding to rock minerals, and of the behavior of mixtures of pairs of such compounds in producing mixed crystals, new compounds or eutectic mixtures, are of the first importance. The accuracy of the methods employed and the thoroughness of the work guarantee the value of the results and their permanency. In addition to the establishment of improved, or entirely new, methods of operation of a purely physical character tributary to the study of petrological problems, they have determined the isomorphism and physical behavior of the lime-soda-feldspar series; the relations of the various lime-silica compounds to one another; those of the lime-magnesia-metasilicate series; the melting and transition points of quartz and tridymite, and the character of still other compounds, and they have materially extended our knowledge of solid solutions.

Doelter and his pupils have studied the fusibility of the rock minerals and their solubility in one another, but the methods employed are less accurate than those just mentioned and involve a large element of subjectivity. They are approximations to the facts desired, often of much value qualitatively, but sometimes misleading. Other recent and valuable qualitative work in this field has been done by Morozewicz, while earlier work is represented by the classic researches of Daubrée, Fouqué, Michel-Lévy and others.

The most obvious result of the earlier efforts was the demonstration of the adequacy of fusion and gradual cooling, at ordinary atmospheric pressures, to bring about the crystallization of many minerals found in igneous rocks; and the necessity of some catalytic agency to promote the crystallization of other minerals common to these rocks. Such actions were ascribed to "mineralizing agents," or "crystallizers," assumed to be in most instances dissolved

gases, chiefly H_2O . One of the most significant facts brought to light by the researches of Day and his colleagues is the new conception of high viscosity found in alkali-feldspars and quartz. Viscosities so great at temperatures near the transition point of liquid to crystal phase as to be indistinguishable within the two phases. That is, the viscosities of the amorphous glass and of the crystallized mineral are so nearly identical that the two phases of the substance react alike toward mechanical stress. Molecular mobility is so slight that readjustment from crystalline arrangement to the homogeneous chaos of liquid molecules is accomplished with such extreme slowness that the time of ordinary laboratory observation is not sufficient for its detection. However, the time available for ordinary "geological" processes, so called, is sufficient, as shown by the devitrification of volcanic glasses composed of these constituents—ancient rhyolitic obsidians. The function of a catalytic agent, as a gas dissolved in such a viscous liquid, is obvious—the viscosity is reduced and molecular mobility increased. If the transition is toward the liquid phase, solubility of the crystal is increased. If it is toward the crystal phase, the rate at which crystallographic molecular arrangement is accomplished is increased. The dissolved gas becomes a "crystallizer," or "mineralizing agent." Other substances, such as mineral compounds, yielding less viscous liquids than those of the alkali-feldspars and quartz, when dissolved in the more viscous liquids, reduce their viscosity in the same manner, though not to the same extent, as dissolved gases. They must behave catalytically toward crystallization, as gases do. Their behavior in this respect has not been generally recognized, though the function of certain liquid compounds, as fluxes, or as "mineralizing agents," is well known.

Thus the improvement in methods of

physical research is steadily enlarging the field of petrological investigation, and the advancement in the knowledge of physico-chemical laws is furnishing the investigator with new tools for the work and more efficient means for attacking the problems of igneous rocks. Foremost in the ranks of those who have attempted the application of modern conceptions of physical chemistry to the elucidation of the phenomena of texture and mineral composition and of the genetic relationships of igneous rocks is Vogt, whose earlier studies of furnace slags opened the way for the explanation of many analogous phenomena in the more refractory, volcanic lavas. Chief among these are the apparent order of crystallization of different minerals in slags, as indicated by their shapes and relations to one another as inclusions, and the relation between these orders and the composition of the mixture from which they crystallized. Vogt's observations were found to be in accord with modern theories of solutions, as Bunsen foretold in 1861, when he affirmed his belief that rock magmas are solutions of silicate compounds liquid at high temperatures. Vogt has called the attention of petrologists to these modern theories as developed by Arrhenius, van't Hoff, Ostwald, Gibbs, Meyerhoffer, Roozeboom and others. He has also made definite application of them to some of the phenomena and relationships mentioned. His publications have extended widely the horizon of modern petrology, which by the assumption of these broader, deeper phases of the study of igneous rocks, and of similar problems affecting metamorphic rocks, has passed beyond the narrower boundary of petrography, strictly so called.

The evolution of chemistry from a state of pure empiricism to one of comparatively logical sequence has placed before us a collection of coordinated laws, which, while incomplete, or subject to numerous excep-

tions, furnishes us with means to postulate reactions between the constituent elements of rock magmas with reasonable assurance of correctness, or to explain the formation of mineral compounds hitherto in a measure enigmatical. Much remains to be more firmly established, both as to the chemical character of the elements and their compounds, and with regard to theories relating to their reactions, and even to the very nature of their existence in some instances. The silicate compounds constituting igneous rocks remain largely uninvestigated, so far as concerns their synthesis and reactions in mutual solution. And the physical study of solutions and of their transitions to the solidified components—especially the more complex mixtures—is far from completed. The present is a period of transition in the development of petrology, as were also times past. But the changes taking place at this time appear to be so many and so fundamental that it may well be asked whether the older methods of approach to the study of igneous rocks should not be replaced by others more in accord with present conditions of knowledge of chemistry, physics and of the rocks themselves. The older method, in the nature of things, was, and is largely at the present day, objective, and the expressions of relationships or laws empirical.

It would seem more reasonable to begin a systematic study of igneous rocks with a consideration: of the most fundamental characteristics of the magmas from which they have solidified; of their constituents, together with their probable chemical reactions and the resulting mineral compounds; of the manner in which these may separate from a silicate solution, or rock magma; of the shapes they are likely to assume upon crystallization and the consequent texture of the rock. Processes of molecular separation of magmas lead to the discussion of the differentiation of magma into chem-

ically unlike parts and the resulting different varieties of igneous rocks, together with their eruption and solidification as geological bodies of various kinds.

Assuming a certain elementary acquaintance with rocks on the part of the student, which is acquired in courses in general geology, the systematic treatment of the subject should begin by calling attention to the chemical composition of unaltered igneous rock as shown by analyses, published in many descriptions of rocks, but most conveniently found in comprehensive collections in *Bulletins of the U. S. Geological Survey* and in the tables of analyses edited by Justus Roth and more recently by H. S. Washington. The extremely variable nature of these data and their great abundance present such an exceedingly complex set of numerical relations that their statement, or discussion, requires the aid of diagrams by which the problem may be greatly simplified.

In addition to the chemical elements noted in ordinary rock analyses there is a much greater number known to occur in rare minerals that crystallize from rock magmas in special instances, or that oftener appear in certain varieties of igneous rocks, such as the pegmatites. A consideration of all known pyrogenetic minerals with respect to their chemical composition calls attention to the compounds that are repeatedly formed in igneous magmas by the union of the elements that existed in the magmas before their solidification. And by arranging them in accordance with the order of their constituent elements in the Mendeléeff series valuable information as to certain chemical relationships among these compounds is at once furnished.

The substances occurring in igneous rocks are in most cases solids, less often liquids or gases. The solid compounds are always in crystallized condition. Amorphous, glassy solids that sometimes occur in igneous rocks

are seldom, if ever, definite chemical compounds, but are mixtures. The crystallized substances (minerals) are rarely present as uncombined elements, such as gold, graphite and metallic iron. A few are simple compounds with invariable composition, as SiO_2 (quartz), TiO_2 (rutile), Al_2O_3 (corundum). Most of them are complex and variable in composition, owing to the presence of isomorphous mixtures, as the feldspars, olivine, amphiboles. There are very few examples of polymorphism, such as quartz and tridymite. The apparent difference in the crystallization of orthoclase and microcline is probably due to submicroscopic multiple twinning in the apparently more symmetrical form. Polymorphism of some of the pyrogenetic compounds, as MgSiO_3 and CaSiO_3 , which is known in laboratory products is not clearly developed in pyrogenetic minerals.

Certain isomorphous mineral compounds are not developed in igneous magmas with like frequency, or in certain cases not at all. Such, for example, are the hexagonal compounds $\text{NaAlSi}_3\text{O}_8$ (sodium-nephelite), KAlSi_3O_8 (kaliophilite), $\text{LiAlSi}_3\text{O}_8$ (eueryptite). Compare also the potash-, lithia- and soda-micas. Other compounds that are analogous chemically and might be expected to crystallize isomorphously in igneous magmas have quite different crystal symmetry, as is the case with $\text{KAl}(\text{SiO}_3)_2$ (leucite), $\text{NaAl}(\text{SiO}_3)_2$ (jadeite), $\text{LiAl}(\text{SiO}_3)_2$ (spodumene).

Various silicate compounds involving different silicic acids: orthosilicic, metasilicic, polysilicic and in rare instances disilicic, besides uncombined silica, may crystallize from the same rock magma. And even base-forming elements, as iron and aluminum, may, under some conditions, separate from rock magmas as oxides without combining with silica, which may itself separate as SiO_2 . That is, hematite, magnetite or corundum may crystallize in the pres-

ence of quartz. On the other hand, certain lower silicates do not form when there is sufficient silica to form higher silicates with the same bases. Thus $KAl(SiO_3)_2$ (leucite) and $NaAlSiO_3$ (nephelite) do not occur pyrogenetically with SiO_2 (quartz).

Moreover, it is well known that some rock magmas, especially those of intermediate composition, crystallize under one set of conditions into certain combinations of minerals, and under others into other combinations, certain minerals appearing in one case and not in another, though the magmas from which they formed were chemically alike.

In order to account for the production of the mineral compounds known to occur in igneous rocks, as well as for the absence of others; and to understand the possibility of variation in the production of mineral compounds from any magma under variable conditions; and to comprehend the act of separation and crystallization of such minerals upon the solidification of the magma; it is necessary to consider the probable physical and chemical character of liquid rock magmas, especially the known physicochemical laws regarding solutions.

Discussions of the behavior of solutions under varying conditions of temperature and pressure involve theories of the possible molecular constitution of matter, gaseous, liquid and solid, which must be kept in mind in order to form any clear conception of the processes under consideration. The kinetic theory regarding the behavior of molecules of gas, liquid or solid, under variable temperatures and pressures, furnishes definite pictures of changes of state at transition points from one phase to another. Those with which the problems before us are most concerned are the critical point of gases, the melting point of solids, the solution or the separation points of solids in liquids and also the

transition point between two crystal phases of the same compound (such as that between quartz and tridymite).

Since liquid rock magmas are solutions of silicate compounds in one another, all that is known of the physical and chemical behavior of solutions is germane to the discussion. This includes the solution of gases, liquids and solids, in liquids; and eventually their solution in solids; the solubility of various substances in liquids of other substances; the possible molecular constitution of liquid solutions; the existence of molecules of different degrees of complexity, and the dissociation or ionization of some compound molecules; the laws relating to diffusion, and the relative diffusibility of various compounds; those relating to the molecular concentration—the saturation and supersaturation of solutions. The chief qualifying factors in this discussion are the chemical composition of the several compounds; the possibility of changes in chemical equilibria; the viscosity of the solution; the temperature, pressure and the time through which any operation acts. The possibility of producing in a colloidal condition one of the compounds, $Al(OH)_3$, $Fe(OH)_3$ or $Si(OH)_4$, by the interaction of the hydroxyl (OH) and aluminium (Al), iron (Fe), or silicon (Si), is also to be taken into consideration.

In a solution containing the chemical elements common to igneous rocks reactions should take place between them in accordance with known chemical laws, and with results corresponding to observed pyrogenetic mineral compounds. Some of the fundamental laws relating to chemical reactions among the elements are based upon conceptions of chemical energy and activity, and of the conditions that modify their effects. An important factor in chemical processes is, often, a catalytic agent that promotes reactions without itself appearing as a component of the final products. The

chemical behavior of ionic substances, and especially the hydrolyzing action of ionized water, are other factors in the problem under consideration. The relative strength of chemical activity in the base-forming, or acid-forming, elements, and their ability to form acids and salts, lead to the discussion of the production of the pyrogenetic minerals from liquid magmas composed of elements found in igneous rocks; some of these minerals having been produced in the laboratory by melting together the component elements in proper proportions.

Considering what should take place in a solution having the composition of an average of all igneous rocks, it can be shown, since the chief acid-forming elements present are silicon in large amount, and the more active element phosphorus in very small amount, that salts with these elements in the acid radical must be common. Other acid-forming elements occurring in small amounts are titanium and zirconium; while iron and aluminium may play this rôle under favorable conditions. The more active, phosphoric, acid forms unstable salts with the active base-forming metals, potassium and sodium, but a very stable compound with the less active metal, calcium, into which compound fluorine, or chlorine, enters; yielding apatite, an almost universal component of igneous rocks.

Silicon is known in the laboratory to form one definite acid, H_4SiO_4 , orthosilicic acid; and other acids of silicon have not been isolated and identified. But very definite mineral compounds exist that indicate that salts from other silicic acids form under proper conditions. These are:

- H_4SiO_4 , orthosilicic acid;
- H_2SiO_3 , metasilicic acid;
- $H_2Si_2O_5$, polysilicic acid;
- $H_2Si_2O_6$, disilicic acid.

It is significant that in laboratory experience with orthosilicic acid, H_4SiO_4 , prepared from aqueous solutions, the com-

pound may be made to lose water gradually until nothing but silica, SiO_2 , remains. In this way free silica may be separated from a silicate compound, a hydrogen silicate; since an acid may be considered as a hydrogen salt.

Observations upon the pyrogenetic minerals, and laboratory experience with synthetic operations, show that salts of several kinds of silicic acids form by the side of one another, and that their character and amount depend on the nature of the base-forming elements present in the mixed solution. Orthosilicates, metasilicates and polysilicates commonly form in the presence of one another, sometimes accompanied by uncombined silica. And it becomes more and more evident that the formation of the different kinds of silicic acid ions, or their salts, is controlled primarily by the strength, or chemical activity, of the base-forming elements; is dependent also on the amount of silica available in the solution; and may be modified, of course, by other factors. Thus it appears that the most active metals command the highest silicic ions, the highest silicates common in igneous rocks being the polysilicates of the alkalis, potassium and sodium—orthoclase and albite.

Further, the abundance of aluminium in most rock magmas results in the presence of abundant aluminous compounds. And this element, which is relatively inactive chemically, being found sometimes in the basic, sometimes in the acid radical, is oftenest combined with the strongest base-forming elements, potassium and sodium. These relations are illustrated by the following common, simple pyrogenetic minerals.

It is well known that the orthosilicate of sodium and aluminium (nephelite) and the metasilicate of potassium and aluminium (leucite) do not form in the presence of free silica (quartz), while metasilicates

and orthosilicates of the less active metals, calcium, magnesium and iron (pyroxenes, olivine and anorthite) do. The relative chemical activity of all of the elements common to igneous rocks may be illustrated in like manner, and the probabilities of various pyrogenetic mineral compounds forming from different rock magmas may be made clear.

One of the most important factors in the discussion of the chemistry of igneous rocks is the rôle of hydrogen, whether as an active base-forming element, or as a catalytic agent, alone, as hydrogen (H), or combined with oxygen, as hydroxyl (OH). Its exact behavior in each specific case is not definitely known, but the principles applicable to several distinguishable cases are clearly established.

Adopting the idea that an acid is a hydrogen salt in which hydrogen plays the rôle of a positive, base-forming element, an acid salt may be considered as one in which all of the hydrogen has not been replaced by other base-forming metals. Such an acid salt may be looked upon as a substitution derivative from a hydrogen salt (acid), or from a normal salt by the introduction of hydrogen in place of other positive metals. An example of such a compound among pyrogenetic minerals is to be found in muscovite (K, H)Al(SiO₄). This might be derived from H₄SiO₄,

KAl(SiO₄) or Al₄(SiO₄)₃. The formation of such a compound involves the presence of active hydrogen to play the rôle of metal. Muscovite is a common pyrogenetic mineral in some igneous rocks rich in silicon, with much uncombined silica, and also in others comparatively low in silica, accompanying orthosilicate and nephelite. It forms by the side of polysilicates—orthoclase and albite—and even with the disilicate, petalite. The formation of muscovite must be ascribed to the action of hydrogen upon silicon, either directly in the first instance, or, if previously formed silicates of aluminium and potassium be assumed to be the source of the compound in question, then its action in replacing part of the potassium must be that known as hydrolysis, whereby the hydrogen ions from water replace metals in the salt through a process of double decomposition.

It is known that the chemical activity of hydrogen even toward a gas, like oxygen, is greatly increased by rise of temperature; hydrogen being rather inert at ordinary temperatures. The relative activity of hydrogen and potassium toward silicon is indicated by the fact that the highest hydrogen silicate definitely known is the orthosilicate, H₄SiO₄ (orthosilicic acid), whereas potassium commonly occurs in a polysilicate, KAlSi₃O₈ (orthoclase). It has been found impossible to produce mica in open cru-

cibles from which hydrogen, or water vapor, naturally escapes at high temperatures. And muscovite is not formed pyrogenetically in surface lavas, or, if so, to a very small extent as compared with its occurrence in rocks crystallized under considerable pressure. From these facts it must be concluded that the formation of the acid orthosilicate (muscovite) in the presence of polysilicates and free silica must be assigned to the chemical activity of hydrogen at high temperatures under sufficient pressure to hold it in the liquid magma solution.

The same argument as to the action of hydrogen in rock magmas applies to the production of the other micas, biotites and lepidolite. These compounds are complex mixed salts, and the composition of biotite involves the production of orthosilicates of magnesium and iron, which are present in biotite. These orthosilicates develop in magmas together with metasilicates of magnesium and iron—pyroxenes and hornblende—and with uncombined silica, quartz. The same compounds when alone form olivine, which generally does not develop in magmas with uncombined silica, quartz, but probably occurs with quartz oftener than has been supposed. In both of these cases the production of orthosilicate of magnesium and iron in the presence of "free" silica in magmas in which the metasilicate might be expected to form is probably due to the hydrolyzing action of water at high temperature. That is, the hydrogen at high temperature combined with some of the silicon, that otherwise would have united with magnesium and iron as metasilicate, and formed orthosilicate of these metals and orthosilicate of hydrogen.

Should conditions of saturation favor the

separation of the magnesium-iron compound in the solid phase, olivine would crystallize; and with falling temperature the hydrogen silicate would split up into water (H_2O) and silica (SiO_2), with the eventual crystallization of quartz.

When the amount of silica is great as compared with that of magnesium-iron orthosilicate it is possible for quartz to separate before the orthosilicate, as is the case in many hollow spherulites and lithophysæ, where fayalite, $(\text{Fe}(\text{Mg}))_2\text{SiO}_4$, is apparently almost the last mineral to crystallize, and rests upon the surface of abundant quartzes. The dependence of these forms of crystallization upon the presence of water in the magmas has been clearly demonstrated.

Other mineral compounds, whose production in igneous rocks must be referred to the hydrolyzing action of water, are amphiboles, which, as Penfield has shown, contain as an essential constituent notable amounts of hydrogen. The development of hornblende in igneous rocks appears to be dependent on conditions similar to those controlling the development of biotite, for they commonly accompany one another in rocks of intermediate composition when either is present. The particular kind of amphibole which forms in rock magmas depends primarily on the proportions of elements present, and secondarily on attendant conditions which produce variation in amphibole from one magma, which is strikingly illustrated in the two igneous rocks from Gran, Norway, described by Brögger.² The magmas have almost the same chemical composition, yet one crystallized into a mixture of hornblende and lime-soda-feldspar, while the other crystallized almost completely into hornblende, which contains all the components of the

² Brögger, W. C., "Erupt. Gest. kp. Geb.," Vol. III., 1899, p. 93, and *Quart. Jour. Geol. Soc.*, Vol. L., 1894, p. 19.

feldspar and hornblende in the first-mentioned rock.

That hornblendes are less stable compounds in igneous magmas than pyroxenes and numerous other minerals, is shown by the frequent occurrence of paramorphs of other minerals after hornblende, commonly seen in so-called black borders, and the absence of correspondingly changed crystals of other minerals.

Another chemical principle involved in the production of pyrogenetic minerals is that affecting the formation of compounds that possess common ions when in solution. It is known that when there are in a solution ions capable of entering two or more compounds, the concentration of the least soluble compound may be increased by the entrance of ions derived from other compounds into its molecules. And this may proceed to the complete incorporation of the common ions within one compound upon its separation in the solid phase. This has sometimes been called erroneously "mass action." That compound forms at the expense of another in any particular instance which is the more stable under attendant conditions. Illustrations of this action are found: in the case of the complex amphibole in the hornblendite of Gran already mentioned; in aluminous pyroxenes (augites), which contain components capable of forming lime-soda-feldspars, as pointed out by Pirsson, and in numerous other rock minerals. This principle is probably concerned in the production of the lime-soda-feldspars with notable amounts of albite molecules, as in andesine and labradorite, in magmas so low in silica as to necessitate the production of leucite from the potassium present, when the more active potassium should have combined with the silicon in a polysilicate (orthoclase), leaving the less active sodium to enter orthosilicate (nephelite).

Following out the discussion of all the probable compounds likely to form under known chemical laws from molten rock magmas upon cooling, and taking into consideration the relative chemical activities of the several constituent elements in igneous rocks, it is possible to deduce a probable mineral composition for any given magma, under given conditions of cooling. The mineral composition of igneous rocks then becomes a necessary consequence of the chemical reactions likely to obtain in molten rock magmas, and depends not only on the kinds and amounts of the elements present in each case, but also on the conditions of temperature and pressure modifying the chemical activities of the elements and the stability of the compounds. As these conditions are known to vary with the experience of different magmas during eruption and solidification, the minerals produced in chemically similar magmas are not to be expected to be always alike, and the variations in composition are in this way understood.

Having considered the possible chemical reactions that may give rise to mineral compounds in rock magmas, the next step in the treatment of the subject is a discussion of the process and results of separation of various compounds or substances from magma solutions upon change of physical conditions attending the eruption of magmas. These may separate as gases, liquids or solids, chiefly as solids. But gases escape in large volumes upon the eruption of lavas, mostly as water vapor. There are other kinds in smaller, though often in considerable, amounts. The effects of this loss of gases are in the chemical composition of the rock magma, in the concentration of the remaining substances, and in the viscosity of the magma, which may increase notably upon loss of gas.

Liquids, probably, do not separate as such from molten magmas to any consider-

able extent. Apparently liquid silicates are miscible in one another in all proportions, though suggestions that they may not have been advanced by some petrologists. It is known that liquid sulphides and silicates are not miscible in all proportions at all temperatures. And where sulphides exist in large amounts, separation in the liquid phase may take place with falling temperature.

Separation of solids from solution depends upon the attainment of a sufficient molecular concentration of substances to saturate the solution. Saturation may be brought about in several ways: by chemical reaction within the solution consequent upon a change of chemical equilibrium; by change of temperature, usually by lowering temperature; by change of pressure, either acting in an opposite manner from temperature or by affecting the gas content.

Solids may separate when the point of saturation for them has been reached, or the liquid may become superheated, and separation be delayed. In this condition separation is often induced by the insertion of a solid of like composition, or of an isomorphous compound, or by agitating. Such a condition of a liquid has been called *metastable*, and in this condition, as shown by Miers in laboratory observations on liquids of organic compounds, crystallization of the separating substance takes place, at relatively few points, and proceeds gradually, according to degree of concentration and other factors, until comparatively large individuals are formed. If supersaturation proceeds without separation of solid phase a point will be reached when separation will take place spontaneously at many points in the liquid and continue rapidly. This is the *labile* condition of the liquid. When this condition is reached by a cooling liquid crystallization often takes place suddenly as a

shower of minute individuals, as observed by Miers. The bearing of these facts on the textures of igneous rocks is apparent, and a knowledge of the laws relating to the separation of solids from liquids; the order in which those of different substances may follow one another in a mixed solution; the separation of isomorphous compounds; and the shapes that may be assumed by the resulting crystals of various minerals lead to an understanding of the texture of igneous rocks.

A supersaturated condition is more readily obtained in more viscous liquids, which are more apt to solidify without crystallization, as glasses, than more fluid liquids. The most familiar illustrations of this law among igneous rocks are the persilicic (rhyolitic) lavas, which often form glasses (obsidians). The question has been raised by Crosby, and others, whether an earthquake happening when a magma was in a sufficiently supersaturated, metastable, condition might not induce crystallization of some of the constituent compounds.

Crystallization may begin with different degrees of supersaturation of the liquid, and would proceed at different rates according to the degree of supersaturation, being more rapid the greater the concentration. It would also be more rapid the greater the molecular diffusivity, that is, the lower the viscosity of the liquid, and the greater the rate of cooling, so long as this does not increase viscosity too rapidly. Gradual or slow crystallization at comparatively few centers would yield relatively few, large, crystals; whereas sudden, rapid crystallization from many centers would produce many small ones.

High fluidity in solutions would permit easy diffusion of separating molecules toward crystallizing centers, favoring the growth of relatively large individuals. High viscosity would retard diffusion and

favor the growth of many small crystals. This is well illustrated by the laboratory experience of Day with the crystallization of various lime-soda-feldspars. Thus it was found that 100 grams of liquid anorthite crystallized completely in ten minutes to fair-sized crystals, and it required quick chilling to prevent its crystallization and to produce glass. A mixture of equal parts of anorthite and albite (Ab, An_1) required a gradual cooling extending over several days to effect complete crystallization, whereas liquid albite could not be induced to crystallize through days of cooling in an open crucible. Comparing the size of the crystals of anorthite produced in 10 minutes with those of oligoclase-andesine (Ab, An_1) which were produced by gradual cooling through two days, the former were from 3 to 5 mm. thick, the latter about 0.005 mm. thick. That is, the more liquid anorthite produced crystals one thousand times as thick in about one three-hundredth the time, a ratio of 300,000:1.

The rate of separation of solid from liquid also depends on the solubility and the amount of any substance in solution. The greater each of these factors the more rapid the rate of crystallization and the larger the crystals, other things being constant in compared cases. This law has been expressed definitely by von Pickardt as follows: "The velocity of crystallization (separation in solid phase) is diminished by the addition of foreign substances to the liquid phase of a substance, the diminution of the velocity being the same for equimolecular quantities of all substances."

The order of succession in the separation of different kinds of minerals from molten magma is a subject upon which there has been some difference of opinion among petrologists. It has been clearly demonstrated that the order is not an in-

variable one. The laws relating to the order of separation of solids from mixed solutions have been definitely determined for solutions of various compounds in one another and the general principles are applicable to the study of igneous rocks. The attention of petrographers has been called to these laws by Vogt.

The order of separation of several compounds in solution in one another depends on the degree of saturation of each, that with the highest degree of saturation, or that one whose saturation point is reached first upon the cooling of the solution separates first. The relation between saturation, molecular concentration and the melting point of each compound has been established in general terms for different sets of cases by Meyerhoffer, and further elaborated by Roozeboom for cases of crystals of isomorphous compounds.

In all cases where the mixed compounds do not unite chemically to form new compounds, or physically as mixed crystals, there is one minimum point of temperature for a mixture of two compounds, and more than one in more complex mixtures, at which a certain proportioned mixture remains liquid. At this temperature the two components of a binary mixture will crystallize simultaneously. This minimum temperature and particular mixture are called eutectic.

Miers has shown that when supersaturation sets in and the labile condition is taken into account, the minimum temperature of separation and corresponding proportions of the mixture do not coincide with those already described as eutectic. These he has called hypertectic.

A study of these principles shows that there can be no invariable order of separation, or crystallization, of the constituent compounds in a series of mixed solutions composed of like compounds. And that simultaneous crystallization of pairs, or of

more than two kinds of separating compounds, may take place in solutions of whatever composition. Eutectic mixtures may consist of more than two components. Moreover, the supersaturation of a solution by one component may affect the proportion between two or more components at the moment of synchronous crystallization. Synchronously crystallized mixtures of certain kinds of components, therefore, are not necessarily similarly proportioned. The bearing of these principles on the crystallization and texture of igneous rocks is manifold. A few illustrations will suffice. Quartz may be the first mineral to separate from a molten magma when the solution is so rich in silica that upon cooling it becomes saturated with silica before being saturated with feldspar or some ferromagnesian compound, or even iron oxide. Quartz may be the last mineral to separate from magmas so rich in feldspar or ferromagnesian compounds as to become saturated by these upon cooling before being saturated with quartz.

Either labradorite or augite may separate first from a mixture of the two, according to which saturates the solution first upon cooling, and this depends on their relative amounts in the solution, and their order of crystallization is further modified by the possibility of one or the other producing supersaturation in the liquid. This will account for the differences of texture often noted in certain gabbros, or basalts, of almost the same composition.

Eutectic mixtures, or those whose components crystallize simultaneously, often yield aggregates of intergrown crystals, the most familiar examples of which are found in graphic granite, and certain alloys. But Miers has called attention to the fact that the simultaneous crystallization of two compounds in eutectic proportions does not invariably produce intergrown individual

crystals, or graphic intergrowths. It may result in granular aggregations of concerted, adjacent anhedral not intergrown, which corresponds to observations on the textures of igneous rocks, for many rocks of like composition in some instances exhibit graphic texture, in others evenly granular texture. Accepting graphic intergrowth as evidence of synchronous crystallization, and of the existence of eutectic proportions in some cases between the several mineral compounds at the moment of crystallization, it is to be noted that such intergrowths have been developed in igneous rocks between quartz and potash-feldspar, quartz and sodic feldspars, quartz and biotite, feldspar and pyroxene, feldspar and hornblende, feldspar and nephelite, pyroxene and iron oxide (probably magnetite) and between other pairs of minerals.

The separation of solids, that is, the crystallization of minerals from rock magmas, must be an extremely intricate process, because of the complex character of the solution, the variable and irregular changes in temperature and pressure consequent on the movements of eruption, the variations in composition due to changes in gaseous components, and the possibility of chemical reaction among the components with changes of chemical equilibria, as well as the probable supersaturation of the magma by different components to various degrees. This complexity will doubtless prevent exact statements of the relations between composition and texture, but approximations may be made to the proper explanation of some of the most common and characteristic textures, which will render them more intelligible to the student.

The crystallization of a substance from solution involves molecular diffusion, and molecular orientation, and these are functions of molecular attraction, composition of the molecular compound, viscosity of the

liquid, composition of the liquid, temperature, pressure and time, or rate of changing conditions. The combination of these factors in the case of any cooling rock magma results in rock possessing a certain degree of crystallinity, which may range from a state of complete crystallinity, to the reverse, or complete glassiness. When more or less crystalline, the size of the crystals becomes a feature of consequence. The granularity, or the size of crystals in rocks, has been given a prominent rôle in most descriptions, and classifications of rocks. The shapes of individual crystals clearly give distinctive character to the pattern, or fabric, of rocks, and shape is largely a function of crystal structure and physical habit of specific minerals. The recognition of these relationships and their systematic treatment in the description and discussion of igneous rocks will lift the subject out of a maze of confusing, complex detail, usually treated in an uncoordinated and meaningless manner.

Application of principles of molecular diffusion; of laws relating to solution pressure, or osmotic pressure; of conditions controlling crystallization, or the separation of solids from solutions; of conditions affecting the physical character of liquids, or rock magmas; to the observed variability in the composition of igneous rocks, and to the known relation between their composition, order of eruption, and mode of occurrence, leads to conceptions of their origin from other magmas, by processes called by the general designation of *differentiation*.

With such an understanding of the causes of heterogeneity in rock solutions the great variability in the composition of igneous rocks as shown by chemical analyses, and by a quantitative study of their mineral composition, appears as the natural, as well as the logical, result of their mode of formation.

Mineralogical and constitutional facies of igneous rocks are readily comprehended; and the absence of fixed types of magmas, or of frequently recurring bodies of igneous rocks with definite or invariable composition, becomes "natural," and is the thing to be expected. Variations in texture within one rock mass, and among rock bodies having various modes of occurrence, are readily understood as the results of variability in the conditions attending volcanic eruption.

As to the possible character of volcanic eruption, some conception of it may be derived from a consideration of the probable condition of highly heated rock material under great pressure deep beneath the surface of the earth, as well as its probable experience in moving upward and out upon the earth's surface.

The high temperature of volcanic lavas when they reach the atmosphere, the fact that they were losing heat continually from the time of their first movement upward, the evidence that they were completely liquid at some stage in their eruption, together with the observed gradient of increase of temperature downward from the surface of the earth, all combine to show that rock magmas come from some region where the temperature is considerably above the melting point of igneous rocks. The behavior of the earth as a rigid globe, and the known effect of pressure in counteracting that of heat, together with its estimated high gradient of increase downward within the earth, force the conclusion that at sufficient depth magma, though hot enough to be liquid, behaves as a solid. Such conditions of heat and pressure can not vary abruptly from place to place, but must be nearly the same for large volumes of material; and differences of temperature and pressure must obtain very gradually, chiefly in vertical directions. Magma in

such a position must be in a virtually static condition until it experiences change of pressure or stress. Whatever its composition, it must remain unchanged.

A change of stress may come about by movement in the overlying portion of the earth. Orogenic movement, readjustment of the upper rigid, rock mass, from whatever causes, when profound, must affect the stresses in still deeper parts. The known crustal movements behave as bendings of the upper rock mass, which in places at the earth's surface appear to result in tensile stresses; in places, in compressional stresses. Beneath each of these the effective stresses must be of the opposite kind; under the tensile, compressive stresses, and under the upper compressive ones, tensile stresses. Tensile stresses should occur at some distance below ocean beds, and more especially along the borders of oceans and continents. Compressive stresses should occur, in general, beneath continental masses.

Tensile stress, as at the bottom of a synclinal arch, operating in a rigid mass must communicate itself downward as far as the mass behaves rigidly. When the hot mass is potentially fluid, that is, is kept solid by pressure, change of stress must be followed by change of position of the mass. A tendency to pull apart or stretch in the potentially fluid mass must be followed by a yielding of the mass. At a point sufficiently cool for the mass to act as a solid a tendency to fracture and to open a fissure would be followed by a movement of the slightly more heated mass beneath to occupy the space between the fractured solid; these differences of temperature and of rigidity are to be understood in a mathematical sense as differential, there being a gradation of physical conditions between adjacent parts of the mass. There will be no open space, or fissure, in the ordinary

sense. But it must be understood that at whatever depth the mass may be considered solid, there it may fracture, part and become the walls of a layer or body of intruded liquid, provided the liquid have nearly the same density as the solid mass.

The statement made by Van Hise and Hoskins that open cracks, or fissures, can not exist at greater depths than about 10,000 meters was made on the assumption that the filling is water; the difference in weight of the rock and the hydrostatic pressure of the corresponding column of water being compared with the crushing strength of the solid rock. When the liquid is heavier than water the same method of calculation allows fissures filled with such liquid to exist at greater depths; and if the weight of the column of liquid equals that of the wall rock, the two will remain in equilibrium at any depth. Consequently at any depth in the earth mass where a tendency to part may exist, hotter and potentially more fluid material beneath may move up and permit the parting of the slightly more rigid mass to take place. This would appear to be the initial step in the eruption of rock magma.

As the mass shifts its position upward the pressure upon it decreases, resulting in some expansion of the volume, some decrease in density, some increase in mobility. And the rising mass is hotter than the masses between which it is rising, unless movement is at the same rate as the diffusion of heat. In proportion as the tensile stress is strong the upward movement will be pronounced, and may result in a flow of very dense, hot, viscous magma toward the surface of the earth. The greater the vertical distance traversed and the more rapid the rate of movement, the greater the difference in temperature between the magma and the enclosing mass.

That the eruption of rock magma is con-

sequent upon the adjustment of accumulated stresses within the overlying rocks is indicated by the sequence of fractures and lava flows in the uppermost parts of the earth, and the opening of eras of great volcanic activity after profound orogenic movements have disturbed the comparatively quiet action of forces that have been gradually shifting the stresses within the outer portion of the earth. The magnitude of the adjusting action is evinced by the extent of territory simultaneously affected. As, for example, the initiation of volcanic action on a gigantic scale throughout western America at the end of Cretaceous time, after an enormous period of nearly uniform conditions of comparative quiet.

The eruptive impulse, or energy, causing the upward flow of magma, must originate in the expansion of the magma upon relief of pressure consequent upon the adjustment of stresses in the overlying mass, and from expansive energy of dissolved gases. That the eruptive force is of nearly the same order of magnitude as the stresses within the earth's crust is shown by the relatively small amount of material erupted upon the surface of the earth compared with the bulk of the whole; by the common intrusion of magma along fracture planes and along those of structural weakness, rather than at random through rock masses; and most conspicuously, by the evidence of equilibrium with the atmosphere maintained by lava in volcanic craters. Open vents are known to exist for centuries without great extrusion of rock magma, as at Stromboli. The stresses which produce condensation of volume in proportion to depth and the results of expansion of volume are, therefore, somewhat evenly balanced.

The effect of expanding gases is shown in the explosive character of many eruptions, and the periodic character of all eruptions from open vents (volcanoes). It must increase the volume of all magmas

as pressure is relieved. Its effectiveness must increase in proportion to the amount of gas in the magma, which may result from diffusion of gas from greater depths of magma, and also from accession from adjacent rocks under favorable conditions.

Spasmodic eruption may follow sudden yielding of overlying rocks to long continued stresses, as in the case of massive, or fissure, eruptions when there may have been no considerable explosive action of gas; or it may result from an accumulation of gas pressure sufficient to rupture overlying rock masses. Eruption is then accompanied by abundant evidence of explosion. Both causes undoubtedly operate together in most cases.

In so far as magmatic eruption is a result of volumetric expansion of the magma, due to relief of pressure, the shrinkage of volume due to cooling will retard eruption, or eventually stop it. Crystallization will operate in the same direction. In proportion as eruption is due to expansion of dissolved gas, the escape of gas from magma, or the reduction of supply, will lessen the force of eruption, or eventually put an end to it. The supply of gas from great depths may be reduced by the gradual diffusion of whatever is in a position to be appreciably diffused; or the supply from rocks adjacent to intruded magma may be cut off by the closing of pores in these rocks through metamorphism; porous rocks becoming dense and almost impervious to gases. In these ways eruptive action initiated by crustal readjustment after continuing for variable periods may come to an end. Readjustment of stresses may recur from time to time in any region, either at such widely remote periods that the volcanic activities associated with each readjustment constitute distinct and separate periods of action; or at such frequent intervals that the results of several profound movements are combined to form a

prolonged period of complex volcanic eruptions.

Independence of action at neighboring volcanoes, either as to period of eruption, volume of magma erupted, explosive or quiet character of action, or relative height of lava column in conduit of volcanoes, follows from local variation in the factors entering into the process of magma eruption, such as, the volume of magma involved in each conduit extending to profound depths, the shape of the conduit, the temperature of the magma; the rate of cooling; the amount of gas diffused in any given time; the character of the surrounding rocks; and the stability of the surrounding rock masses as a complex whole. The chemical composition of the magma is also a factor involved in the activity of a particular volcano. But the composition of the magma is also a feature by which volcanoes may show independence. Differences in the composition of rocks in neighboring volcanoes is to be sought in variation in the differentiation of magmas during the course of eruption from deep-seated to surficial positions.

Among the results of such differentiation may be mentioned the production of complementary rocks, which may occur in rock bodies of various forms. A special case of local differentiation, usually associated immediately with crystallization and solidification of parts of a magma, is the production of contemporaneous veins and pegmatites. When complementary rock magmas are erupted so close to one another in space and time that they come in conjunction while still highly heated, they may diffuse into one another, or blende to such an extent as to yield hybrid rocks, or mixed dikes, sheets, etc., as observed by Harker on the Isle of Skye.

The eruption of rock magmas through solid rocks and their solidification in various positions within or upon other rocks condition the modes of occurrence of igne-

ous rocks, as those of lava streams, dikes, sheets, laccoliths, etc. And the parting or cracking of the solid rock, upon cooling, or its arrangement after fragmentation in various ways leads to distinctive structures, such as columnar, spheroidal or brecciated.

Having acquired a knowledge of the general principles applicable to all igneous rocks, it is in order to consider more specifically those occurring in all known parts of the world: first, systematically, according to some comprehensive scheme of arrangement, or classification, and then according to the groups, or associations, in which they occur in various regions, that is, according to petrographical provinces, or co-magmatic regions.

In order to describe many rocks a nomenclature is necessary, and the confusion existing in that in present use is best understood by considering the history of the growth of petrography, and the changes that have gone on in the definition and use of the oldest and commonest rock names, and descriptive terms. With this review should be associated a sketch of the development of rock classification, which has been furnished to the student in an interesting form by Cross.

A successful treatment of the subject of igneous rocks along the lines indicated would go far toward the removal of petrology from a state of distracting empiricism, and the placing of it on a more rational foundation.

JOSEPH P. IDDINGS

WASHINGTON, D. C.

CONDUCT OF SCIENTIFIC WORK UNDER THE UNITED STATES GOVERNMENT¹

To the Senate and House of Representatives:

In compliance with the provisions of section 8 of the act of Congress making appropriations

¹Message from the President of the United States, transmitting a report of the National Academy of Sciences relating to the conduct of the scientific work under the United States government.

for sundry civil expenses of the government for the fiscal year ending June 30, 1909, approved May 27, 1908, I transmit herewith for the consideration of the Congress the report of the National Academy of Sciences relating to the conduct of the scientific work under the United States government.

THEODORE ROOSEVELT

THE WHITE HOUSE,
January 18, 1909

NATIONAL ACADEMY OF SCIENCES,
OFFICE OF THE PRESIDENT,
Baltimore, January 16, 1909

Sir: The sundry civil act approved May 27, 1908, requests the National Academy of Sciences to consider certain questions relating to the conduct of the scientific work under the United States government, and to report the result of its investigations to Congress.

Immediately after the passage of the act a committee, consisting of five eminent men of science, none of whom held employment under the United States government, was appointed to make the necessary investigation. The members of that committee are:

R. S. Woodward, president of the Carnegie Institution of Washington, chairman.

W. W. Campbell, director of the Lick Observatory, Mount Hamilton, Cal.

Edward L. Nichols, professor of physics, Cornell University.

Arthur A. Noyes, acting president of the Massachusetts Institute of Technology.

Charles R. Van Hise, president of the University of Wisconsin.

Under date of January 9, 1909, this committee submitted its report to the council of the academy.

I have the honor to transmit herewith this report to Congress.

I am, sir, very respectfully,

IRA REMSEN,

President National Academy of Sciences
THE SPEAKER OF THE HOUSE
OF REPRESENTATIVES

REPORT OF COMMITTEE ON CONDUCT OF SCIENTIFIC
WORK UNDER THE UNITED STATES GOVERNMENT
*To the Council of the National Academy of
Sciences:*

During the first session of the Sixtieth Con-

gress of the United States there was incorporated in the act making appropriations for sundry civil expenses of the government for the fiscal year ending June 30, 1909, the following section, namely:

SEC. 8. The National Academy of Sciences is required, at their next meeting, to take into consideration the methods and expenses of conducting all surveys of a scientific character and all chemical, testing and experimental laboratories and to report to Congress as soon thereafter as may be practicable a plan for consolidating such surveys, chemical, testing, and experimental laboratories so as to effectually prevent duplication of work and reduce expenditures without detriment to the public service.

It is the judgment of Congress that any person who holds employment under the United States, or who is employed by and receives a regular salary from any scientific bureau or institution that is required to report to Congress, should refrain from participation in the deliberations of said National Academy of Sciences on this subject and from voting on or joining in any recommendation hereunder.

In compliance with the terms of this legislation, the president of the National Academy of Sciences appointed the undersigned committee to consider the questions specified in said legislation, with a view of securing a report on or before the next annual meeting of the academy. This committee now has the honor to submit a report.

It should be explained, first, that in compliance with a request addressed by the president of the academy to the President of the United States, all of the executive departments of the government were directed to assist the representatives of the National Academy of Sciences in securing such information as might be necessary in preparing this report. The communication from the President of the United States announcing that such direction had been issued bears the date June 29, 1908. In conformity therewith numerous communications have been received by your committee from heads of departments and from bureaus and divisions of the government engaged in the kinds of work specified in the legislative act cited above.

In the second place, it should be stated that this committee has had access to the unpub-

lished preliminary report of a committee appointed by the President of the United States March 13, 1903, to consider many of the same questions here reported upon and others closely allied thereto. The chairman of the latter committee has also placed at our disposal a large mass of data collected by that committee.

In the third place, it should be stated that the members of your committee have been chosen in strict conformity with the requirements of the second paragraph of the legislative act quoted above.

A comprehensive interpretation of the functions of your committee shows that the field work for consideration is very large, and that it presents many difficulties requiring the most careful study before any final recommendations for legislative or executive action may be safely made. Nearly every department of the government is involved to a greater or less extent, while some departments, like the Department of Agriculture and that of Commerce and Labor, are carrying on scientific work in a great variety of ways. Thus, to illustrate the extent and variety of this work, it may be stated that surveys are now being carried on by seven different organizations under five different departments of the government; similarly, tests of apparatus, materials, foods, etc., are being made by the Bureau of Standards, by the technologic branch of the Geological Survey, by the Department of Agriculture, and to a minor degree by many other departments and bureaus of the government. Similarly, chemical work is carried on in many branches of the Department of Agriculture, by the Bureau of Standards, by the Geological Survey, by the Public Health and Marine-Hospital Service, and to a less extent by other branches of the public service.

It should be borne in mind also, in considering the present status of these organizations carrying on scientific work, that many of them have been so long established as to become integral parts of the departments to which they are assigned. Hence, any considerations looking to a consolidation or to a redistribution in the departments of these organizations should take into account their origin and historical development as well as their present

status. The experience gained through a long series of years by these organizations should indicate what special merits they possess as well as the defects of organization and efficiency they may now present.

In view, therefore, of the importance of the scientific work now carried on by the government, and in view of the certain prospect that it will increase rather than decrease in the future, your committee is disposed to look at the problems presented by this work with a desire rather to furnish constructive criticism and advice than to recommend any immediate and radical changes based on destructive criticism, however well founded the latter may be in some cases. In other words, it appears more important to your committee to provide for enlightened and efficient conduct of governmental scientific work in the future than to be influenced to any considerable degree by the imperfections of organization and the inefficiencies in conduct of that work in the past.

From a general survey of the field of work under consideration three facts appear to be clearly established, namely:

First. That the amount of actual duplication of work now carried on by the government bureaus is relatively unimportant: but that the duplication of organizations and of plants for the conduct of such work is so considerable as to need careful attention from Congress in the future.

Second. That while the consolidation of some branches of work now carried on in several organizations is probably advisable, specific recommendations in reference to such consolidation can be made wisely only after a careful consideration of all the facts by the board hereinafter suggested or by some similarly competent body.

Third. That there has never been hitherto and there is not at present anything like a rational correlation of allied branches of scientific work carried on by the government.

This last fact appears to your committee by far the most important one presented for consideration. The lack of any well-defined plan for the development of such work, its distribution in various departments, and the lack of any systematic scheme of interrelations of the

bureaus carrying on this work have led inevitably and properly to the questions submitted by Congress to the academy.

It is plainly desirable, therefore, that Congress should make immediate provision to guard against a continuance of the evils which arise from a lack of any definite plan for, and from the absence of any adequate correlation of, the scientific work of the government.

It appears to your committee that the best way to deal with the condition now confronting the government is to secure the appointment by Congress of a permanent board which shall meet at stated intervals in each year for the consideration of all questions of the inauguration, the continuance, and the interrelations of the various branches of governmental scientific work. We would suggest that such a board should consist of the heads of bureaus carrying on scientific work, of two delegates from each of the Houses of Congress, and of five to seven eminent men of science not connected with the government service.

By means of a few meetings per year, with authorization to secure the requisite information from the heads of departments and bureaus concerned, all of the complicated questions which now are at best only ill considered could be carefully determined with great advantage in point of economy and efficiency to the public service and with little or no additional expense thereto.

Such a board could take under consideration the prevailing lack of system and lack of correlation in the work in question and gradually remove these defects from existing bureaus and divisions of the public service. All questions of the assignment, of the conduct, of advisable consolidation, and of the economies of such work could be fully discussed and determined in the best interests of the government by such a board. If the heads of bureaus and divisions were required to submit their projects and estimates for work to this board before transmission to the heads of departments and to Congress, all questions of the duplication of work, of the duplication of organizations, of the duplication of laboratories or equipments, and of the most economical assignment could be readily determined

without interference in the details of management of the organizations concerned.

One of the most important functions of such a board should be that of the nomination or selection of men competent to take charge of new projects or to fill vacancies which may arise in the more important positions of the scientific work in question. It would thus be generally possible to prevent the assignment of an incompetent man to the charge of a highly technical or specialized branch of the public service. It would thus be possible also to secure men of the highest professional attainments and to prevent the calamity which has not infrequently occurred in the past of assigning important scientific work to unprofessional or incompetent men. It would thus be possible likewise to take advantage of the competition between different branches of the public service in the laudable desire of those branches to prove their efficiency by the accomplishment of the required work of the government in the best and most economical ways.

Very respectfully submitted.

R. S. WOODWARD,

Chairman,

W. W. CAMPBELL,

EDWARD L. NICHOLS,

ARTHUR A. NOYES,

CHARLES R. VAN HISE

WASHINGTON, D. C.,

January 9, 1909

RECENT WORK OF THE MOUNT WILSON SOLAR OBSERVATORY

MONOCHROMATIC photographs of the sun have been made daily on Mount Wilson since October, 1905, with the Snow telescope and five-foot spectroheliograph. The weather has been very favorable, permitting calcium, hydrogen and frequently iron images to be taken on 303 days in 1908, and on 113 consecutive days during the summer of 1907. Prior to March, 1908, the hydrogen photographs were made with the light of the violet line $H\delta$. Since that time, with the aid of plates sensitized by Wallace's formula, excellent results have been obtained with the red hydrogen line $H\alpha$. These record the phenomena of a region in the solar atmosphere higher than that previously

explored, and reveal the existence of extensive vortices or cyclonic storms associated with sun-spots. In general, the direction of rotation of the vortices is counter-clockwise in the northern hemisphere and clockwise in the southern, as in the case of terrestrial cyclones; but a few interesting exceptions, in which the direction of rotation was reversed, have been found. There can now be little doubt that what we see in the telescope as a sun-spot is the mass of vapor, cooled somewhat below the temperature of the photosphere, which lies at the center of an invisible vortex (*Astrophysical Journal*, Vol. XXVIII., pp. 100-16).

The discovery of these vortices suggested that the rapid revolution of electrically charged particles, emitted from carbon and other vapors at the high temperature of the sun, should produce a magnetic field in sun-spots. Tests made with the 30-foot spectrograph of the tower telescope show all the characteristic phenomena of the Zeeman effect in the spot spectrum, and leave no doubt as to the existence of a magnetic field. The strength of the field has been found to range from about 2,800 to about 4,500 gauss in different spots. Vortices rotating in opposite directions show opposite polarities, the changes in the spectrum and in the polarization phenomena being precisely similar to those of a luminous source in a magnetic field when the current through the magnet is reversed. The results indicate that the magnetic field is produced by the revolution of negative corpuscles in the vortices (see *Astrophysical Journal*, Vol. XXVIII., pp. 315-343). There is some evidence that the plane of polarization of light passing through the spot vapors is rotated through different angles in different parts of the umbra, but more observations of this phenomenon are needed. For this and other purposes a tower telescope 160 feet high, giving a solar image 16 inches in diameter, and a spectrograph 75 feet long, mounted in a well below the tower, should prove of the greatest service. These instruments are now being designed, and will soon be constructed in our Pasadena shop.¹

¹ This telescope, of small aperture (12 inches) and great focal length (150 feet), is designed exclusively for work on the sun, where a large

The above results are of some general interest, since they conclusively demonstrate for the first time the operation of electric phenomena in the sun. So far as the cause and nature of sun-spots are concerned, they seem to favor Emden's theory. An attempt is now being made to determine whether the sun as a whole is a magnet. The tests already completed indicate that extremely sensitive methods will be required to settle the question, and these will soon be applied.

The 60-inch reflecting telescope, which has been under construction in our instrument and optical shops during the last four years, is now in operation on Mount Wilson. Visual and photographic tests show this instrument to be of the highest optical and mechanical perfection, and reflect great credit upon Professor Ritchey, its designer, and those who have been associated with him in the extensive work of construction and erection. Photographs of nebulae made by Professor Ritchey, and a series of photographs of the great nebula in Orion, made through a red screen by the writer, are of exquisite sharpness and perfection of detail. The star images are extremely small, and the wealth of faint stars shown leaves no doubt that in light-grasping power, as well as in optical resolution, the telescope will meet our highest expectations. One of the most gratifying results of these tests is the proof they afford of the excellence of the night conditions on Mount Wilson. For the last four consecutive nights (January 16, 17, 18, 19) the definition with the full aperture of 60 inches has been essentially perfect from a photographic standpoint. This is in the midst of the rainy season, when the atmosphere is far less steady than during the unbroken succession of clear days and nights of summer. A telescope of 100 inches aperture, or even larger, could certainly be used here to great advantage on nights such as we have already tested. Fortunately, Mr. John D. Hooker, of Los Angeles, has agreed to meet the expense image is required. The 60-inch and 100-inch reflecting telescopes, of great aperture and smaller focal length, are not suitable for solar observations, but will be used for the study of stars and nebulae.

of constructing a large mirror for this observatory. A disk of glass 100 inches in diameter and 13 inches thick, weighing $4\frac{1}{2}$ tons, has recently been received at our Pasadena shop from the French Plate Glass Works at St. Gobain, France. Much time was consumed in filling our order, and it was hoped that the disk would prove suitable. This does not turn out to be the case, however, and another trial must be made. The observatory will experience no financial loss, as the disk had not been accepted. The loss in time will not be very serious, because of the great opportunities for research in unexplored fields afforded by the 60-inch reflector. I have no doubt that the difficulties of making a homogeneous disk of these great dimensions will soon be successfully overcome, and that the Hooker telescope will be ready in time to extend the work of the 60-inch reflector into territory which even this powerful instrument can not enter.

GEORGE E. HALE

BROOKS MEMORIAL

IN the Donovan room of McCoy Hall, Johns Hopkins University, the end of the old and beginning of the new year saw a memorable reunion of men who had worked in contact with Professor W. K. Brooks. Under the guidance of the chairman, Professor S. F. Clarke, many paid tribute to Brooks, the inspiring teacher, whose life at Williams and at Cambridge was vividly sketched by Professor Edward A. Birge, and whose career at the Johns Hopkins furnished the material for many pleasant recollections and expressions of esteem and of love by Professors E. B. Wilson, H. W. Conn, H. H. Donaldson, F. H. Herrick, M. M. Metcalf and others who were Brooks's pupils in later years.

Upon motion of Professor Harrison a committee was appointed to prepare a memorial volume in honor of their master.

Professor E. L. Mark and thirty-two other zoologists of Harvard, in attendance upon the scientific meetings in Baltimore, wrote to express their "sentiments of highest appreciation for the character of the work of William Keith Brooks."

It was hoped that the incidents of Professor Brooks's life at Penikese could be made vivid by one who was there with Brooks, but a telegram from President David Starr Jordan stated his regret that he could not be present to honor the memory of "the wisest of American naturalists." Others were also unable to come to Baltimore. The names of the sixty men actually present follows below:

Edward A. Birge, fellow student at Williams College, professor of zoology, University of Wisconsin.

Samuel Fessenden Clarke, Ph.D., 1874, professor of natural history, Williams College.

Edmund Beecher Wilson, Ph.D., 1881, professor of zoology, Columbia University.

Albert H. Tuttle, professor of biology, University of Virginia.

Basil Sollers, student, 1878-9, teacher in public schools, Baltimore.

William Henry Howell, Ph.D., 1884, professor of physiology, Johns Hopkins University.

Herbert William Conn, Ph.D., 1884, professor of biology, Wesleyan University.

Henry Herbert Donaldson, Ph.D., 1885, professor of neurology, University of Pennsylvania.

Frederick Schiller Lee, Ph.D., 1885, professor of physiology, Columbia University.

James Playfair McMurrich, Ph.D., 1885, professor of anatomy, University of Toronto.

Albro David Morrill, Beaufort Laboratory, 1885, professor of biology, Hamilton College.

George Theophilus Kemp, Ph.D., 1886, sometime professor of physiology, University of Illinois.

Louis J. Rettger, student, 1886-9, candidate for Ph.D., 1900, professor of physiology, Indiana State Normal School.

Charles L. Edwards, graduate student, 1886-9, professor of natural history, Trinity College.

F. L. Washburn, graduate student, 1886-7, state entomologist, Minnesota, and professor of entomology, University of Minnesota.

Edwin Linton, Beaufort Laboratory, professor of zoology, Washington and Jefferson College.

Ethan Allen Andrews, Ph.D., 1887, professor of zoology, Johns Hopkins University.

Henry Gustav Beyer, Ph.D., 1887, medical inspector, United States Navy.

John Pendleton Campbell, Ph.D., 1888, professor of biology, University of Georgia.

Francis Hobart Harrick, Ph.D., 1888, professor of biology, Adelbert College.

Henry Van Peters Wilson, Ph.D., 1888, professor of biology, University of North Carolina.

Arthur Lincoln Lamb, A.B., 1888, science master, Country School, Baltimore.

Clifton Fremont Hodge, Ph.D., 1889, assistant professor of physiology, Clark University.

Thomas Hunt Morgan, Ph.D., 1890, professor of experimental zoology, Columbia University.

Henry Torsey Fernald, Ph.D., 1890, professor of entomology, Massachusetts Agricultural College.

Edwin Grant Conklin, Ph.D., 1891, professor of zoology, Princeton University.

Robert Payne Bigelow, Ph.D., 1892, instructor in biology and librarian, Massachusetts Institute of Technology.

George Wilton Field, Ph.D., 1892, zoologist, Massachusetts Board of Fisheries.

Theodore Hough, Ph.D., 1893, professor of physiology, University of Virginia.

Maynard Mayo Metcalf, Ph.D., 1893, professor of zoology, Oberlin College.

Herbert Spencer Jennings, professor of experimental zoology, Johns Hopkins University.

Ross Granville Harrison, Ph.D., 1894, professor of comparative anatomy, Yale University.

Reid Hunt, Ph.D., 1896, pharmacologist, Bureau of Health, Washington, D. C.

Henry McElderry Knowler, Ph.D., 1896, associate in anatomy, Johns Hopkins University.

George Lefevre, Ph.D., 1896, professor of zoology, University of Missouri.

Hubert Lyman Clark, Ph.D., 1897, assistant in invertebrate zoology, Harvard University.

Charles Peter Sigerfoos, Ph.D., 1897, professor of zoology, University of Minnesota.

Duncan Starr Johnson, Ph.D., 1897, professor of botany, Johns Hopkins University.

Gilman Arthur Drew, Ph.D., 1898, professor of biology, University of Maine.

Caswell Grave, Ph.D., 1899, associate professor of zoology, Johns Hopkins University.

Albert Moore Reese, Ph.D., 1900, professor of zoology, West Virginia University.

William Chambers Coker, Ph.D., 1901, associate professor of botany, University of North Carolina.

Henry Farnham Perkins, Ph.D., 1902, assistant professor of zoology, University of Vermont.

Lewis Robinson Cary, student, 1903-5, holder of fellowship, Princeton University.

Rheinart Parker Cowles, Ph.D., 1904, instructor in biology, Johns Hopkins University.

Otto Charles Glaser, Ph.D., 1904, instructor in zoology, University of Michigan.

David Hill Tennent, Ph.D., 1904, associate professor in zoology, Bryn Mawr College.

Eugene Willis Gudger, Ph.D., 1905, professor of biology and geology, North Carolina Normal and Industrial College.

John Augustine English Eyester, M.D., 1905, associate professor of physiology, University of Virginia.

Samuel Rittenhouse, Ph.D., 1905, instructor in biology, Olivet College.

Robert Irvine Coker, Ph.D., 1906, special investigator for Peruvian Government.

Bartgis McGlone, Ph.D., 1907, professor of biology, St. John's College.

Ivey Foreman Lewis, Ph.D., 1908, professor of biology, Randolph-Macon College.

William E. Kellicott, lecturer, 1908, professor of biology, Woman's College, Baltimore.

Samuel Ottmar Mast, Johnston scholar, 1907-8, associate professor of biology, Woman's College.

J. Frank Daniel, Adam T. Bruce, fellow, 1908-9, Johns Hopkins University.

William Dana Hoyt, fellow in botany, 1908-9, Johns Hopkins University.

Asa Arthur Schaeffer, fellow in zoology, 1908-9, Johns Hopkins University.

Frederick Harvey Blodgett, candidate for Ph.D., 1910, Johns Hopkins University.

William Henry Brown, candidate for Ph.D., 1910, Johns Hopkins University.

SCIENTIFIC NOTES AND NEWS

As has already been announced, Sir J. J. Thomson, F.R.S., will preside over the Winnipeg meeting of the British Association to be held from August 25 to September 1 of this year. The presidents of the sections are as follows: A (Mathematical and Physical Science), Professor E. Rutherford, F.R.S.; B (Chemistry), Professor H. E. Armstrong, F.R.S.; C (Geology), Dr. A. Smith Woodward, F.R.S.; D (Zoology), Dr. A. E. Shipley, F.R.S.; E (Geography), Sir Duncan A. Johnston, K.C.M.G.; F (Economic Science and Statistics), Professor S. J. Chapman; G (Engineering), Sir William H. White, K.C.B., F.R.S.; H (Anthropology), Professor J. L. Myres; I (Physiology), Professor E. H. Starling, F.R.S.; K (Botany), Lieut.-Colonel D. Prain, F.R.S.; L (Educational Science), Dr. H. B. Gray; and subsection, Agriculture, Major P. G. Craigie (chairman).

Mr. H. B. Woodward, F.R.S., having reached the age of seventy-six years, has re-

tired from the assistant directorship of the Geological Survey of Great Britain. He is succeeded by Dr. H. Strahan, F.R.S.

M. LÉON L'ABBÉ, who has recently been re-elected to the French senate, succeeds M. Bucquoy as president of the Paris Academy of Medicine.

MR. ARTHUR SILVA WHITE has resigned as assistant secretary of the British Association for the Advancement of Science.

PROFESSOR HILLHOUSE will retire from the chair of botany in the University of Birmingham at the end of the present session.

MR. R. JAMES WALLACE, who has for several years past been engaged in photographic research at the Yerkes Observatory, as instructor in photophysics, has resigned his position there to become director of the research laboratory of the Cramer Dry Plate Company at St. Louis. It is a promising evidence of appreciation of research that a commercial company engages the services of a scientific investigator for the improvement and further development of its products.

THE Geological Society of London will this year award its medals and funds as follows: Wollaston medal, Mr. Horace B. Woodward, F.R.S.; Murchison medal, Professor Grenville A. J. Cole; Lyell medal, Professor Percy F. Kendall; Bigsby medal, Dr. John Smith Flett; Prestwich medal, Lady Evans; Wollaston fund, Mr. Arthur J. C. Molyneux; Murchison fund, Mr. James V. Elsdon; Lyell fund, Mr. R. G. Carruthers and Mr. Herbert Brantwood Muff.

DR. JOHN M. COULTER, head of the department of botany in the University of Chicago, was among those who returned to New York on the *Baltic* after the ill-fated trip of the steamer *Republic*.

We learn from *Nature* that Professor J. Arthur Thomson, of Aberdeen University, has been invited by the lecture committee of the South African Association for the Advancement of Science to give the "South African Lectures" for 1909. The lectures are to be delivered in August and September in Johannesburg, Pretoria, Bloemfontein, Kimberley,

Cape Town, Grahamstown and Durban, and at the request of the committee they will have special reference to the Darwin centenary.

MR. G. W. BURY has undertaken an expedition into southwest Arabia.

MR. DONALD MACKAY is engaged in exploration in British New Guinea. He is attempting to ascend the Purari River, with a view to making his way overland to the head waters of the Fly River.

DR. C. W. A. VEDITZ, professor of economics at George Washington University, has been selected as a special expert agent for the United States Department of Labor and Commerce to investigate the child-labor problem and conditions in the principal industrial countries of Europe. He will leave this country on February 3 and will remain abroad for about eight months.

PRESIDENT ROOSEVELT has appointed Mr. W. K. Moorehead, curator of archeology in Phillips Academy, Andover, a member of the United States Board of Indian Commissioners.

DR. FRANCIS E. FREMANTLE, medical officer of health for Hertfordshire, has been appointed to the Edward Jenner lectureship in public health at St. George's Hospital Medical School, London.

UNDER the auspices of the Pennsylvania Society of the Archeological Institute of America, a public lecture was given at the University of Pennsylvania Museum on Wednesday afternoon, January 27, on "Excavations and Repairs at Casa Grande, Arizona," by Professor J. Walter Fewkes, of the U. S. Bureau of American Ethnology.

MR. FRED G. PLUMMER, chief of geography in the National Forest Service, gave a lecture on "The American Forests" before the department of geology of Colgate University, on the evening of January 20.

At the regular meeting of the Academy of Science of St. Louis, held on January 18, 1909, with Professor Wm. Trelease presiding, Professor W. H. Roever, of the department of mathematics of Washington University, presented a paper embodying his researches on

"An Optical Interpretation of some Problems in Statistics."

At the meeting of the Royal Microscopical Society on January 20, Lord Avebury delivered his presidential address on seeds, with special reference to British plants.

PROFESSOR KARL PEARSON gave last month before the Royal Institution of Great Britain two lectures on "Albinism in Man."

SIR THOMAS WARDELL, known for his researches on silk fiber, died on January 3, in his seventy-eighth year.

MAJOR PERCY B. MOLESWORTH, who had made valuable observations on Jupiter and Mars, died in Ceylon on December 26, in his forty-second year.

M. DOMINIQUE CLOS, honorary professor of botany at Toulouse, has died at the age of eighty-eight years.

THE House of Representatives has included in the military appropriation bill an appropriation of \$500,000 for air-ships. The Russian war office has reserved for this purpose a fund of \$750,000. The Aero Club of America offers a prize of \$10,000 for a race from New York City to Albany as part of the Hudson-Fulton memorial celebrations to be held in the autumn.

THE sum of \$100,000 has been given to the medical school of the London Hospital, the income to be expended in the advancement of medical research and the promotion of higher education in medicine.

BARON BESSIÈRES has left a legacy of \$16,000 to the Pasteur Institute, Paris, to be employed in scientific researches.

A ROYAL BRITISH RADIUM INSTITUTE is to be established through a gift from Sir Ernest Cassel. It is intended to investigate especially the therapeutic action of radium. In this connection it is reported that a syndicate has been formed in connection with the institute to extract radium from the pitch-blend deposits of an old copper mine recently reopened at St. Ives, Cornwall. This is said to be the only place where radium can be produced outside of Austria.

A SOCIETY of radiology has been founded in Paris for the scientific study of the medical applications of radiations in general.

THE important George G. Heye collection of American antiquities will soon be placed on exhibition in the Museum of the University of Pennsylvania.

Two additions to the series of North American habitat groups in the American Museum of Natural History have recently been completed. These are the Duck Hawk group, representing a scene along the Palisades of the Hudson River, and the Hackensack Meadow group, which represents the nesting habits of the birds which frequent it in August.

A MEDICAL congress is to be held in Bombay, beginning on February 22. Sir George Clarke will deliver the presidential address, and the sectional meetings will last four days.

ARRANGEMENTS for the North American Conservation Conference between representatives of the United States, Canada and Mexico, at the White House, February 18, are going forward rapidly, following the cordial acceptance by Sir Wilfrid Laurier, Premier, and Earl Grey, Governor-General, of Canada, and President Diaz, of Mexico, of President Roosevelt's invitation to send delegates. The conference will discuss the situation with regard to the natural resources of the respective countries and help prepare a general plan adapted to promote the welfare of the nations concerned in accordance with President Roosevelt's suggestion. This International Conference will meet at the White House by President Roosevelt's invitation. It will not be a large gathering as was the Conference of Governors at the White House last May, or the joint Conservation Conference last December between the National Conservation Commission, the Governors and the representatives of State Conservation Commissions and Conservation Committees of national organizations. The attendance will be limited to the representatives of Canada and Mexico and representatives of the State Department of the United States Government and of other executive departments which can render particular assistance to the conferees in their deliberations,

and the National Conservation Commission. Canada has already taken active steps in preparation for the conference and recently sent to the National Conservation Commission a number of carefully prepared maps which show the present status of the public lands of the dominion as well as the distribution of the principal natural resources and the development of its transportation systems. The Canadian authorities have also gathered together and sent to the chairman of the commission a comprehensive collection of government documents bearing on the natural resources of the country. These have been carefully indexed and bound together according to subjects. They will be used at the forthcoming conference.

Mr. D. C. SOWERS, in charge of the special magnetic expedition to China under the auspices of the Carnegie Institution of Washington, left Peking on January 30. He will be assisted by Professor Chester G. Fuson, for the past four years professor of history and geography at the Canton Christian College. The general route to be followed by the party will touch at the following places: Sianfu, Lanchowfu, Suchow, Turfan, Kashgar, Khotan, thence, via the Karakorum Pass, into India, where connection will be made at Dehra Dun with the magnetic survey of India. A series of magnetic observations will, therefore, be obtained in parts of China and Chinese Turkestan where no previous data existed. Dr. J. C. Beattie, director of the department of physics, South African College, Cape Town, has been granted a year's furlough in order to take charge of a magnetic survey party under the auspices of the Carnegie Institution of Washington. He left Cape Town November 25. His general route of travel will be through German Southwest Africa, thence into Rhodesia, British East Africa, German East Africa, and next through Nubia and Egypt, connecting with the magnetic survey of Egypt at Cairo. He will be assisted by Professor J. T. Morrison, in charge of the department of physics, Victoria College, Stellenbosch, South Africa, who will confine his work chiefly to points reached by steamer along the east and

west coasts of Africa. There will thus be obtained during the present year magnetic data in regions of Africa hitherto almost entirely unexplored. Mr. Joseph C. Pearson, who during the past year has been engaged in making magnetic observations in various parts of Persia under the auspices of the Carnegie Institution, will be ready to undertake similar work in Asia Minor, beginning at Bagdad some time in March.

PRIZES conferred by the Paris Academy of Medicine include: the Baillarger prize (£80) to Dr. A. Rodiet, of Dun-sur-Auron, for a contribution to the study of the organization of lunatic asylums; the Barbier prize (£80) has been divided among several competitors, Dr. P. Remlinger, of Constantinople, getting £32 for a series of researches on rabies, Dr. L. Malloizel, of Paris, £24 for anatomo-clinical researches on pleuro-cortical reactions, and Drs. Louis Wickham and Degrais, of Paris, a like amount for their work on the treatment of angiomas of radium. To Professor Calmette, director of the Pasteur Institute at Lille, and MM. Boullanger and E. Rolants, heads of laboratories, F. Constant and L. Massol, demonstrators in the same institute, and Professor Buisine, of the Lille Faculty of Science, has been awarded the Orfila prize (£160) for researches on the purification of water that has been used in towns and of the residual water of factories. Dr. Marfan has won the Roger prize (£100) for his treatise on suckling and the feeding of infants. The Saintour prize (£176) has been awarded to Dr. Emile Sergent, of Paris, for his work on syphilis and tuberculosis; the Campbell-Dupieris prize (£92) to Dr. Morris Nicloux, *Professeur agrégé* of the Paris Faculty, for his work on general anesthetics from the chemico-physiological point of view. The Ernest Godard prize (£40) has been awarded to Dr. F. W. Pavy, of London, for his work on carbohydrates and their transformation—a physiologico-pathological study with considerations on diabetes and its treatment.

THE New York State Bar Association at the closing session of its thirty-second annual meeting at Buffalo on January 29, went on

record in favor of a bill designed to correct the evils of expert medical testimony in the courts. The draft of the bill provides, among other things, that "in criminal cases for homicide where the issues involve expert knowledge or opinion the court shall appoint one or more suitable disinterested persons, not exceeding three, to investigate such issues and testify at the trial; and the compensation of such person or persons shall be fixed by the court and paid by the county where indictment was found, and the fact that such witness or witnesses have been so appointed shall be made known to the jury. This provision shall not preclude either prosecution or defense from using other expert witnesses at the trial."

UNIVERSITY AND EDUCATIONAL NEWS

A BILL has been introduced in the Wisconsin legislature which proposes to increase the building fund of the University of Wisconsin from \$200,000 to \$300,000 annually, and to lengthen the period of this appropriation from five to seven years.

A NEW industrial fellowship has been presented to the University of Kansas by the Holophane Glass Co. It yields \$1,500 a year for two years, together with ten per cent. of the profits that may arise from any discoveries made by the student who pursues the special study. The fellowship is open to students of any university, but the work will be done in the laboratories of the University of Kansas.

BRYN MAWR COLLEGE has established ten graduate scholarships, five open to English, Irish or Scotch and five to German women students, who have attained a standard equivalent to that of the bachelor's degree. The scholarship covers the fees for board, residence and tuition at Bryn Mawr College for one academic year and as these fees for graduate students amount to \$405 this is equivalent to a scholarship of £81 or of 1,620 Marks.

MR. CHINUBHAI MADHOWLAL has given four lakhs of rupees (about \$125,000) to be applied

by the Bombay Government towards the development of science teaching in Ahmedabad, in connection, if possible, with the proposed Curline Institute in Bombay.

THE University of Liverpool has received an offer from Mr. Alexander Elder, to contribute \$50,000 for the establishment of a chair of naval architecture.

ON recommendation of the faculty of the medical department of Western Reserve University, the trustees have voted that beginning with the academic year 1910-11 the requirement for unconditional entrance to the medical department shall be graduation from an approved college or scientific school granting the bachelor's degree (or equivalent) following the completion of a course of at least three collegiate years and including inorganic chemistry, physics, biology and Latin. Conditional entrance will be granted upon the completion of the work of the junior year in the course of an approved college or scientific school enforcing a four-year course (or equivalent degree) including the subject requirements enumerated above, conditioned upon the student obtaining a baccalaureate degree before he enters the third year in the medical school.

DR. A. GRAHAM LUSK, professor of physiology at the University and Bellevue Hospital Medical School has been appointed professor of physiology in the Cornell Medical College.

DR. DANA B. CASTEEL, instructor in zoology in the University of Michigan, has been appointed instructor in zoology in the University of Texas.

CAPTAIN H. G. LYONS, F.R.S., director-general of the survey of Egypt, has been appointed lecturer in geography at the University of Glasgow.

DISCUSSION AND CORRESPONDENCE

THE LAW OF RADIATION

TO THE EDITOR OF SCIENCE: Is it worth while to keep on upholding certain theories, and to wholly neglect certain new facts which tend to undermine the very foundation on which these theories rest? What justification

is there, for instance, in declaring that my "definition for temperature" is erroneous without an accompanying proof showing that Newton's law of radiation is also erroneous? As this particular matter stands, Dr. Reid has simply made a dogmatic assertion, for if Newton's law is true (and I claim to have demonstrated that it is true) it follows as a theoretical necessity that *absolute temperature is a direct measure of the intensity of ether vibration*. If Stefan's law, or any other law except Newton's, can be demonstrated to be true, then, and then only, will scientists be justified in summarily condemning my conclusions.

J. M. SCHAEFERLE

ANN ARBOR, MICH.,
January 4, 1909

AMERICAN SCIENTIFIC PRODUCTIVITY

It is well that we should be reminded by Professor Nichols in his presidential address before the American Association (SCIENCE, January 1, 1909) and by Professor Pickering in his articles in *The Popular Science Monthly* (October, 1908, and January, 1909) that the scientific work accomplished in this country is not commensurate with its population and its wealth, and that Professor Willcox (SCIENCE, January 29, 1909) should reinforce this fact from the awards of the Nobel prizes.

But while we can not too strongly emphasize the circumstance that we are not doing all that we should for the advancement of science and that this is partly due to the fact that the scientific career is not made sufficiently attractive to obtain and retain the best men, nor sufficiently free to enable them to do their best work, it yet seems that the situation is by no means discouraging. The articles mentioned measure our scientific productivity by the eminent men we have. In so far as this is an adequate method, it tends to measure our activity a generation ago; for men do not usually obtain international recognition until long after the work for which it is given has been accomplished.

Professor Pickering finds that of the 87 scientific men who are members of at least

¹ SCIENCE, January 1, 1909, p. 29.

two foreign academies only six are Americans. Each of the two eminent American men of science who is a member of the largest number of academies is in his seventy-third year. It is a striking fact that of the six distinguished Americans, three are astronomers; and astronomy is the only science in which thirty years ago the facilities for research work in this country were equal to those of the leading European nations. Of the remaining three, two have not been engaged in teaching, and the third has been practically freed from teaching for his research work. We may have, in accordance with Professor Pickering's data, but six scientific men as distinguished as 17 in Prussia, 13 in England and 12 in France, but this would represent the relative scientific activity of the country at the time when our universities were only beginning to develop and when research work under the government was only beginning.

The Nobel prizes have, contrary to the instructions of the founder, been, as a rule, awarded to eminent men for work done in the past; and the fact that of twenty-four prizes in the sciences only one has come to America does not discredit our present scientific research. If the provision of Nobel's will had been followed and the prize had been given to the person "rendering the greatest service to humanity," by "having made the most important discovery or invention in the department of physical science," the first two awards should probably have been to Mr. Bell and Mr. Edison.

It is a curious fact that the three subjects in which the Nobel prizes are awarded—physical science, chemistry and medicine—are those in which we are particularly weak. These are the sciences in which the applications are the most direct, and it looks as if those competent to advance these sciences had been carried into practical work. This is contrary to my preconceptions, for I should suppose that when there are large opportunities for practical work, there should also be advances in pure science. Perhaps it is only individual eminence that is here lacking, and we are in fact contributing our share to

The choir invisible
Whose music is the gladness of the world.

We seem to do better in the natural sciences. In geology, zoology, botany, anthropology and psychology, there is probably more research work published here than in any other country except the German empire and the amount of research work published is the most tangible, and perhaps the most exact, measure of scientific activity. I have found that in the *Zeitschrift für Psychologie* there have been more articles in experimental psychology reviewed (selected as the more important articles) from America than from the German-speaking nations combined, and more than ten times as many as from Great Britain. We have also, according to the criterion of membership in foreign academies, the most eminent living psychologist.

The statement made by Professor Nichols and endorsed by Professor Willcox that "the men who have laid the foundations upon which civilization is built have nearly all been teachers and professors" appears to be more correct for Germany than for England. Darwin did not teach, and not one of the five scientific members of the Order of Merit—Hooker, Huggins, Lister, Rayleigh and Wallace—is a teacher. It is a remarkable fact that while Germany has excelled in the quantity of research work accomplished since the development of its universities, England has produced the greatest leaders. The elementary teaching required in our collegiate universities not only absorbs time and energy, but also tends to develop a superficial omniscience and a dogmatic attitude unfavorable to investigation. If we add to this the clerical, administrative and missionary work, which the university president crowds on the university professor, and the distracting need of earning enough money to support his family, there is perhaps reason to wonder that he accomplishes as much research work as he does accomplish.

Fortunately there has been within thirty years a great increase in this country in the number of positions permitting scientific work, and in the opportunities which these

positions offer for research work. Many of our universities have admirable laboratories, and there is certainly a strong sentiment in favor of permitting the professors to use them. We are gradually obtaining university laboratories analogous to the astronomical observatories, where professors will only do so much teaching as is favorable to their investigations. At the same time there has been a notable development of scientific work outside the universities, under the national government, under states and municipalities, in technological work, and recently in the establishment of research institutions such as the Carnegie Institution of Washington and the Rockefeller Institute for Medical Research. The material foundation is already adequate and will be rapidly enlarged. What we need is more men with the ability and spirit which research work demands.

J. McKEEN CATTELL

SCIENTIFIC BOOKS

Qualitative Analyse vom Standpunkte der Ionenlehre. Von Dr. WILHELM BÖTTGER, Privatdozent und Oberassistent am Phys.-Chem. Institut der Universität Leipzig. Zweite, Umgearbeitete und Stark Erweiterte Auflage. Leipzig, Wilhelm Engelmann. 1908.

The first edition of this book was published in 1902. An English translation by Smeaton appeared in 1906, a book of 300 pages. This second German edition is a stately volume of 524 pages; it contains nearly double as much matter as its predecessor and is quite different in arrangement.

The fundamental general and ionic theory is in a division by itself, forming the first 116 pages of the book, and is illustrated by simple but ingenious and instructive experiments, thirty-five in number. These experiments alone would give the book permanent value, but it is worthy of study throughout.

In the chapter on systematic analysis, for example, a method is given, familiar in detail but new in application, for separating the cations of group III.; after treatment of the sulphides with dilute HCl, and filtering, the filtrate containing Al, Cr, Fe, Mn, Zn and

traces of Co and Ni, is heated to drive off H_2S , and cooled; it is then treated with an excess of KOH, oxidized with Br water or H_2O_2 , and filtered. The residue may contain $\text{Fe}(\text{OH})_3$, MnO_2 , and traces of $\text{Cr}(\text{OH})_3$, $\text{Co}(\text{OH})_2$, $\text{Ni}(\text{OH})_2$. The filtrate may contain K_2CrO_4 , AlO_2K , and ZnO_2K_2 . The Cr is tested for by oxidizing an acidulated portion of the filtrate to perchromic acid by H_2O_2 . Another portion of the filtrate is exactly acidulated with HCl, and precipitated by sodium acetate as aluminium basic acetate, thus securing the detection of very small amounts of Al. The filtrate from the oxyacetate contains the Zn which is precipitated as sulphide by H_2S . Iron and manganese are tested for by dissolving one portion of the residue in HCl, and adding KCNS, or $\text{Fe}(\text{CN})_3\text{K}$, and by fusing another portion of the residue with $\text{Na}_2\text{CO}_3 + \text{KNO}_3$. The presence of traces of compounds of Cr, Co, Ni, not interfering with these tests. This method will be found simpler, shorter, and fully as accurate as the barium carbonate method, which is so generally recommended, when Cr, Mn and Fe are all present in the substance analyzed.

In the chapter on solutions the treatment of sulphides and chlorides insoluble in acids is noticeable.

In the chapter on preliminary treatment the introduction of the Hempel reduction methods is praiseworthy.

The phase-rule is entirely omitted; just why it is hard to see. One may say that beginners can not understand it, but this is not a book for beginners. However, as Dr. Böttger is chief assistant in the Leipsic laboratory, he must be credited with due consideration of the theories to be introduced or omitted.

Elementary physical chemistry throws such a flood of light on the problems of analysis that the opponents of its use for this purpose are fewer every year; although among the new manuals are some which practically differ from the older books only in adding the word "ion" to the name of the element, and freely using + and - signs; such books do not illuminate and make no converts.

The present book, it is true, is too large and too detailed for American college students,

but any one who intends to write a laboratory manual—and who does not write one!—will do well to read Dr. Böttger's book carefully.

It would be well if the author should arrange with his American translator to publish an abbreviation of this book for college use, containing the theoretical part and experiments without change, but cutting down the remainder to a third of its present size. This is practicable, as much of the present material should be omitted for college use, and as Dr. Böttger's German is extremely diffuse. Such a book would be very valuable for college students in their second laboratory-year.

The book, as it is, should be studied by graduate students, and especially by teachers, who will find in its pages simple explanations of more than one puzzling phenomenon. It is to be hoped that the book will meet with the recognition which it merits.

E. RENOUF

A Treatise on Chemistry. By H. E. ROSCOE and C. SCHORLEMMER. Volume II.: The Metals. New Edition, completely revised by H. E. ROSCOE and A. HARDEN. Pp. xii + 1436. New York, The Macmillan Company.

Sir Henry Roscoe is to be congratulated most heartily on the revision of the well-known "Treatise on Chemistry." It is seldom that an author lives to see such an extensive work useful through thirty years and at the end of that time appear entirely fresh with all of the most recent developments in theory and application. The book bears the strong personal impress of the author and is delightful reading on account of the intimate historical presentation of the various subjects. The scientific, practical and historical are so nicely interwoven as to make the book most readable and valuable.

The introduction of material on Werner's valence theory, the phase rule, radio-activity, Thomson's corpuscular theory and other recent developments has added much to the value of the book. In addition to these an account of recent work on alloys has been added, although the treatment is not entirely satisfac-

tory. The brief reference to such an important subject as the constitution of steel is to be regretted.

The subject of crystallography, which was formerly given in the volume of the non-metals, has been transferred to this volume and occupies fifty pages. It is fully believed that such special subjects as this and spectrum analysis (25 pages) might be condensed into much smaller space without injuring the value of the book.

The metallurgical and technical processes, as in previous editions, have been satisfactorily treated, and have been brought up to date.

While the chemists will be pleased to have so excellent a statement of his science as this book, he will regret that the author has not drawn more largely from his long experience and given more attention to criticism and generalization.

HENRY FAY

Lead and Zinc in the United States, Comprising an Economic History of the Mining and Smelting of the Metals, and the Conditions which have affected the Development of the Industries. By WALTER RENTON INGALLS. Pp. x + 368, illustrated. New York, Hill Publishing Co. 1908. \$4.

Most publications dealing with the histories of metals have mainly an antiquarian interest. The two leading exceptions to this general rule are found in the great work of Beck on iron, and the more general book of Neumann on the leading industrial metals, as both authors have taken up the statistical, industrial and technical sides, and added them to the usual chronological treatment of the subject.

The present work deals with lead and zinc only, the ores of which frequently occur together and therefore influence each other in treatment. The new departure of this publication lies in the fact that, restricting the field to the United States, it considers the American methods of treatment of the metals from the mine through the smelter to the market of the finished product. The technical processes are given with sufficient details to be

clear even to the reader not especially versed in this branch of engineering.

The time of writing such a work is opportune, as some of the founders of the modern American lead-smelting practise are still actively engaged in their profession, and as the fathers of the first industrial production of zinc are still living; nor could the work have fallen into better hands than those of the author, who is well-known to the mining and metallurgical profession as an engineer, as a writer on subjects relating to lead and zinc, and as the editor of one of our leading technical journals and annuals.

The introduction gives a brief and concise review of the history of the two metals in this country. The first part, which deals with lead, is much longer than the second, devoted to zinc. This was to have been expected, as while lead was first mined in the early part of the seventeenth century, zinc was not produced until two centuries later.

The history of lead begins with an account of the occurrence of lead ores. The discussion outlines the leading geological features of the deposits, but dwells more upon the character and grade of the ores, and upon the industrial conditions which governed the mining operations. This is followed by the chronology of the history of lead-mining, which starts from the first record of 1621, when lead was mined and smelted near Falling Creek, Va., and records the leading events down to 1906. Chapter III. gives a valuable résumé of the development of the blast-furnace practise of smelting silver-bearing lead ores, and of the treatment of silver-free lead ores in the ore-hearth and the reverberatory furnace. It shows how blast-furnace smelting developed from crude beginnings into its present unsurpassed excellence by the application of science to art, and by concentration of operations into large, centrally located plants. In the account of the ore-hearth work the increase in yield by the recovery of fumes receives due consideration. While in smelting the work of Arents, Eilers, Hahn, Raht and others is recorded, in the chapter on refining we should have liked to see mentioned the invention of the Steitz siphon,

which changed the refining practise as did the Arents siphon tap the blast-furnace work, and the systematization of the complications in the Parkes process, which is more largely due to E. F. Eurich than to anybody else, and which forms the basis of the modern American practise. We miss also any record of some early eastern refineries, as, *e. g.*, the Delaware Lead Works at Philadelphia, and other smaller plants around New York. Chapters V.-XII. give a detailed history of the mining and metallurgical operations of the several states and territories. The production of metal at different periods is usually given, although in some cases, *e. g.*, in Montana, the data are missing. The remaining 55 pages of the 255 given to lead deal with the statistics of production, consumption and prices, with the commercial conditions, the tariff on lead, the labor conditions and with trade agreements and combinations.

The second part, which takes up 90 pages, treats of the history of zinc according to the same general plan as followed with lead. The mechanical concentration of zinc ores, which plays such an important part in the treatment, receives a separate chapter. The chapter on the metallurgy of zinc, the author's specialty, contains a critical review of the different types of distilling furnaces which have been and are used in this country; it is a chapter which every metallurgist will study with profit and pleasure.

The book, as a whole, is most satisfactory, as it is replete with valuable information presented in an interesting way. Last, but not least, it has a full index which enables the student to look up points upon which he desires enlightenment.

H. O. HOFMAN

SCIENTIFIC JOURNALS AND ARTICLES

The American Naturalist for January begins with the first part of a paper by Robert F. Griggs, on "Juvenile Kelps and the Recapitulation Theory." J. Stafford describes "The Larva and Spat of the Canadian Oyster," giving special attention to the microscopic stages mostly omitted in the work of W. K. Brooks. Waldemar Jochelson presents

some interesting notes on "Traditions of the Natives of Northeastern Siberia about the Mammoth" and there are other notes on "The Age of Trotting Horse Sires" and "The Influence of Environment upon Animals."

The American Museum Journal for January has articles on "The Duck Hawk, Hackensack Meadow, and Egret Groups," "Two Noteworthy Museums" (the Congo Museum, Brussels, and Senckenburg Museum, Frankfurt), "The International Tuberculosis Exhibition" and "An Ethnological Trip to Lake Athabasca," besides notes, lists of members elected since the last issue, and the lecture announcements.

The Bulletin of the Charleston Museum for December gives an account, with plan, of "The New Building" which contains the collections, library and lecture room. A note on "The History of the Museum" shows that so late as 1843 it was still under the auspices of the Literary and Philosophical Society of Charleston.

The Museum News of the Brooklyn Institute for January contains an article on "The Hontzin," by Geo. K. Cherrie, which gives a very full account of this interesting bird and includes a considerable amount of new information gathered by Mr. Cherrie. A note on the leather-back turtle given by the New York Aquarium, states its weight to have been a little over 840 pounds; extreme length, following curve, 6 feet, 10 inches, from flipper to flipper over shoulders, 8 feet, 9 inches. The Children's Museum section gives "Some Evidences of Progress in 1908" in the matters of increased attendance by both children and teachers, and an increasing use of the collections and library.

BOTANICAL NOTES

PHYSIOLOGY AND ECOLOGY

ALFRED DACHNOWSKI's brief paper on "The Toxic Property of Bog Water and Bog Soil" (*Bot. Gaz.*, Aug., 1908) is an attempt to contribute something to the solution of the problem of bog conditions so far as vegetation is concerned. Studies were made of a bog island in Buckeye Lake in central Ohio which ap-

peared to confirm the observer in the view that bog-water does contain toxic substances.

Geo. F. Freeman tells (*Bot. Gaz.*, Aug., 1908) of "A Method for the Quantitative Determination of Transpiration in Plants," which consists in using phosphorus-pentoxid U-tubes through which a current of air is drawn by an aspirator. This air current previously flows over the enclosed foliage of the plant under examination, and the moisture which it contains (as a consequence of transpiration) is absorbed by the phosphorus-pentoxid. The increase in weight of the latter enables the experimenter to determine the amount of transpiration.

Somewhat like the preceding is Dr. G. J. Peirce's paper on "A New Respiration Calorimeter" (*Bot. Gaz.*, Sept., 1908) in which after pointing out some errors and crudities in some popular lectures and experiments he describes the simple apparatus which he has found useful. Dewar flasks (with double walls enclosing a vacuum) were used, and it was found that these when silvered enabled the experimenter to obtain results that were quite impossible with other apparatus. Dewar flasks are also popularly known as "thermal bottles," but those supplied in chemical glassware are more serviceable and less expensive.

The question of the effect of illuminating gas upon plants is one of much popular interest and has been investigated by Messrs. Crocker and Knight and the results published in a paper ("Effect of Illuminating Gas and Ethylene upon Flowering Carnations") in the *Botanical Gazette* for October, 1908. They find that one part of gas in 40,000 parts of air kills the young flower buds, and that 1 part of ethylene in 1,000,000 parts of air is harmful.

J. F. McClendon's paper "On the Xerophytic Adaptations of Leaf Structure in Yuccas, Agaves and Nolinias" (*Am. Nat.*, May, 1908) brings together a number of interesting structural details in regard to the epidermis, stomata and general leaf-structure of these plants.

Here should be noticed Professor L. H. Harvey's very helpful paper on the "Floral Succession in the Prairie-grass Formation of

Southeastern South Dakota" (*Bot. Gaz.*, Aug. and Oct., 1908) in which he gives a good idea of the vegetation of the region by an unusually clear discussion, aided by carefully selected photographs.

A suggestive paper entitled "A Study of the Variation of the Number of Ray Flowers of Certain Compositae" by Mr. W. Dudgeon recently appeared in the *Proceedings of the Iowa Academy of Sciences* (Vol. XVI.), in which the author shows by careful counts of several thousand heads from different localities, first, that there is a wide variation in the number, and second, that the highest numbers are the same in the different localities. Thus in *Rudbeckia hirta* the rays range from 2 to 28, with the greatest number of heads having 13. *Rudbeckia triloba* ranges from 5 to 14, with 8 as the normal, while in *Helianthus grosse-serratus* the range is from 7 to 25, with 13 as the normal.

Dr. Henri Hus contributes a paper in the February *American Naturalist* to the obscure subject of teratology, under the title of "Fasciations of Known Causation," in which he enumerates four "causes": (1) mechanical, (2) cases where no injury can be traced, (3) fungi, (4) insects. In his paper these are discussed at length, and numerous examples are cited.

ECONOMIC BOTANY

F. C. STEWART, of the New York Agricultural Experiment Station (Geneva), prints an instructive summary of the botanical investigations made in the station during the past twenty-five years. And it is an excellent record, and had the station accomplished no more in this time than is here enumerated in one department alone, it would have fully repaid the state for the money expended. On looking over the paper one is amazed at how much has been done in these twenty-five years. The diseases of more than thirty kinds of plants have been studied, including most of the standard crops of the state, as apple, asparagus, bean, beet, cabbage, carnation, cauliflower, celery, etc. The alphabetical arrangement makes it easy to find what has been done in the study of the diseases of this or that

plant. Incidentally it becomes a handy reference to the literature of the plant diseases investigated at this station.

H. S. Jackson's address on the "Development of Disease-Resistant Varieties of Plants," given before the Massachusetts Horticultural Society, March 14, 1908, and printed in its proceedings, is a clear popular discussion of a most important but poorly understood subject. Recognizing that "spraying is a nuisance at best" the speaker urged that more attention should be given to the development of varieties which are resistant to disease, suggesting (a) the selection of individuals, (b) the selection of varieties and (c) hybridization followed by selection of varieties and individuals. Brief discussions of what has been accomplished in regard to wheat, clover, cow peas, potatoes, tobacco, cotton, etc., are given which will astonish those who have not followed the work of the last few years; the difficulties are candidly pointed out, and something is said as to the cause of immunity, and the possibility of artificial immunity.

Dr. E. M. East's paper, entitled "A Study of the Factors Influencing the Improvement of the Potato" (Bull. 127, Ill. Expt. Station) is valuable not only from a practical standpoint, but also for the history of the potato which is given in the introductory pages. After this, methods of breeding, inheritance of characters in tuber selections (in which the author regards the gain as doubtful), degeneration of varieties (the author concluding that varieties do not run out), mutations, etc., are taken up in succession. The author suggests three possible methods of improvement, viz., (1) crossing of desirable plants, (2) selections of the most desirable fluctuations among the plants and tubers of a variety, (3) selection of discontinuous variations and a study of ways of causing them, and regards the first as most promising.

Here should be noticed J. E. Rockwell's "Index to Papers relating to Plant-Industry Subjects in the Year-books of the United States Department of Agriculture," which will save much time and labor to the botanist who has occasion to refer to the many valuable

botanical papers published in the agricultural year-books.

Three recent papers by Dr. Kraemer in the *American Journal of Pharmacy* are of interest to the plant histologist as well as the pharmacist, viz., "Microscopical and Chemical Examinations of Black Pepper," the same for commercial ginger, and some distinguishing characters of belladonna and scopolia. Each paper is well illustrated by many clear figures.

SPECIAL ARTICLES

SEX DETERMINATION AND PARTHENOGENESIS IN PHYLLOXERANS AND APHIDS

THE phylloxera of the hickories offer exceptional opportunities for a study of sex-determination and parthenogenesis. In some species three generations can be followed within the same gall—two parthenogenetic and one sexual. We can determine the number of males and females that have descended from the same fertilized egg, as well as the influence of external conditions in affecting the number and kind of individuals in each generation. Immense numbers of eggs can be obtained. They furnish also excellent, although difficult, cytological material.

During three years I have studied the cytological aspects of the life cycle and can now present an almost complete account of the remarkable chromosomal changes that occur in connection with sex-determination.

I wish to lay especial emphasis on three points:

1. In many insects it has been found that sex is connected with, or produced by, two kinds of spermatozoa. But in phylloxerans, aphids, bees, ants, in certain saw-flies, in daphnians and in hydatina, the fertilized eggs produce only females. In the phylloxerans and aphids the result is connected with the formation of only functional female-producing spermatozoa—the male-producing sperms degenerate. One may suspect that similar conditions are to be found in the other groups, and the facts of spermatogenesis in the bee, wasp and ant, support such a view.

2. The females that result from the fertilized egg produce subsequently both males and females parthenogenetically. Clearly the egg as well as the sperm contains factors that determine sex. I have found, in fact, that the same method used by the sperm is also made use of by the egg.

3. I wish to raise certain questions connected with the mechanism by means of which males and females are produced. It has generally been assumed that chance alone determines into which sperm the sex chromosomes pass. There are indications in the egg that this mechanism is not a chance result, but that behind it lie a series of preliminary events that are equally to be reckoned with as sex-determining factors.

The life cycle of a typical species of phylloxera consists of the stem-mother (arising from the fertilized winter egg), of a second winged generation (produced by the stem-mother), and of sexual males and females—mere pigmies in size—that come from the winged individuals. The winged individuals are of two kinds, those bearing large eggs that produce the sexual females, and those bearing small eggs that produce the males. Certain species deviate from this rule. I shall refer to one such species later.

Phylloxera fallax has the following chromosomal history. The polar spindle of the egg laid by the stem-mother has twelve chromosomes. One polar body is extruded. Twelve chromosomes remain in all of the eggs and are found in the somatic cells of the winged generation.

The polar spindle of the female egg laid by a winged individual contains twelve chromosomes. One polar body is extruded, and twelve chromosomes remain in the egg to give this number to the somatic cells of the sexual female.

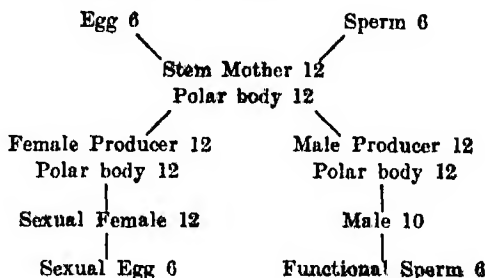

The polar spindle of the smaller male egg also contains twelve chromosomes. One polar body is given off. Ten chromosomes remain in the egg, and this number characterizes all of the body cells of the male, as well as the spermatogonial cells. Evidently two chromo-

somes have disappeared when the polar body is produced.

In the first spermatocytes six chromosomes appear. At the first division four of these divide equally, but two do not divide; they are the accessories or sex chromosomes and pass to one cell. This cell becomes the functional sperm; the other, containing four chromosomes, degenerates. At the second spermatocyte division all six chromosomes in the functional spermatocyte divide equally, so that each of the two spermatozoa gets six chromosomes.¹

The sexual egg contains a polar spindle of six chromosomes. Presumably two polar bodies are formed and six chromosomes remain in the pronucleus.

With these facts we can reconstruct the life cycle of the chromosomes.

Before commenting on these results I wish to call attention to another species, *Phylloxera caryocaulis*.

In this species there are six chromosomes in the polar spindle of the egg laid by the stem-mother. One polar body is extruded. The somatic cells of the embryos contain six chromosomes.

The polar spindle of the female egg contains six chromosomes. Six are given off in the single polar body, and six remain in the egg.

The polar spindle of the male egg also contains six chromosomes, but they are of different sizes from those in the female egg.

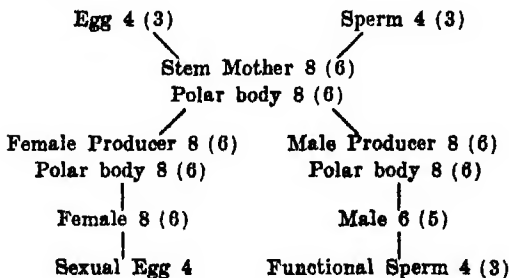

¹ In the aphids also two kinds of spermatozoa are formed. The accessory—single in this case—passes into only one of the spermatocytes. This fact I determined in the winter of 1907-8 and von Baehr and Stevens have also reached the same conclusion (1908).

Six (or more) are given off in the single polar body, but only five are found in many of the male eggs—others contain six (five large and one small). I shall clear up this difficulty later.

In the spermatocytes three chromosomes often appear—at other times four. There are found one or two accessory chromosomes. One cell gets three—or four—the other always two. The former produces the functional sperm; the latter degenerates.

In the second spermatocyte all the chromosomes divide equally in the functional cell. The rudimentary cells do not divide, and later degenerate.

The occurrence of two kinds of males with five or six chromosomes and of two kinds of spermatocytes has given endless trouble and has delayed publication for nearly a year. The facts seem to be these. Eight, not six, is the full number for this species. Two of these chromosomes, one large and one small, often unite. In fact these two are the two accessories and practically always unite to produce a single accessory separating in some individuals as they move into the functional cell. The sexual egg contains four chromosomes. We can construct the chromosomal history as follows:

The most important fact brought out by these results is that in the male egg a redistribution of the eight chromosomes occurs, so that the two small ones pair, and their mates, the two large ones, also pair. This union is evidently preparatory to the extrusion from the male egg of two entire chromosomes which reduces the number in the male by two.

We catch a glimpse here of a mechanism preceding the differential division of the

chromosomes that determines the production of males.

This discovery suggests many further questions. I shall call attention to but one—the most important.

In both species we see that male eggs and female eggs are determined as such before there is any loss of chromosomes. The total number of chromosomes is present, yet one egg is large and the other small. The preliminaries of sex-determination for both sexes go on in the presence of all the chromosomes. The male itself is produced only after the elimination of two of the sex chromosomes, but the sexual female and the parthenogenetic female are both produced in the presence of all of the chromosomes. Clearly, I think, the results show that changes of profound importance may take place without change in the number of chromosomes. Equally clearly emerges the fact that the male develops after the loss of two chromosomes. This latter result shows that in the male parthenogenetic egg sex is connected with the same process found in the sperm of other species of insects.

In conclusion I wish to call attention to the sex ratios in the two species referred to.

Phylloxera fallax produces its sexual forms within the galls. The males and females crawl out of the galls, that open to allow their exit, pair, and deposit the eggs on the stems. A count showed that to 1,067 female eggs there were 1,049 male eggs in the galls—nearly an equality in number of the sexes.

Phylloxera caryocaulis, on the other hand, produces winged forms that leave the gall and fly out in the air. Those that alight on the leaves of the hickory deposit their eggs on the under sides of the leaves. In this species a count of eggs on the leaves gave 1,316 male eggs and 296 female eggs, i. e., nearly 4.4 to 1. More important are the counts of male and female producers within each gall. A large number of such counts have been made, of which the following give a fair idea: These results show a large preponderance of male producers; they also show that in some cases only male producers appear and in one

Male Producers	Female Producers	Male Producers	Female Producers
120	1	229	0
23	8	300	14
331	105	185	0
32	1	127	0
106	2	219	29
152	177	209	9
291	0	0	328
240	0	3	386
323	3		

case only female producers. When it is recalled that all the descendants can be traced to a single egg fertilized by a "female-producing" sperm the results are significant. It is obvious that while the sex of the fertilized egg is connected with the "female-producing" sperm, the subsequent progeny may be either males or females or a mixture of both. Either external conditions determine the result (for which there is no evidence), or else there is a strong "prepotency" of the egg or sperm in one or the other direction.

When it is recalled that the division into male layers and female layers takes place one generation prior to the formation of the sexes, it will be manifest that the conditions that determine the proportion of males and females, *i. e.*, sex-determining factors, are to be sought in a mechanism that lies behind the one that excludes two chromosomes from the male egg.

Equally important is the fact that in the latter process of elimination the result is not haphazard, for the eliminated chromosomes always pass into the polar body of the male egg. Since we can identify this egg before the elimination, we know that we are dealing here also with an ordered series of events, and not with an accidental shifting of chromosomes into one or another cell.

COLUMBIA UNIVERSITY

MOMENTUM EFFECTS IN ELECTRIC DISCHARGE

IN SCIENCE of July 17 and December 4, the writer has given some account of experiments which seem to indicate momentum effects, in electrical discharges around a right angle in a wire. One interesting feature of

the work was the formation of shadow pictures of thin glass slides upon which lines had been scratched. At the Baltimore meeting of the American Association for the Advancement of Science, a series of these pictures was shown, some of which were of special interest.

A sheet of hard rubber one sixteenth of an inch in thickness was pierced with a large number of holes of various diameters. This sheet was laid upon the photographic film within a hard rubber holder. The wire angle from which the fogging effects came was just above the cover, and about 5 mm. from the film. The holder rested upon a sheet of glass, 2 or 3 cm below, which was a grounded metal plate. The film was more strongly fogged at the bases of the larger holes than at those of the smaller ones. The electrons were apparently deflected to the sides of the smaller holes to such an extent that few of them reached the film at the bottom. Holes directly below the wire gave images with sharp outline. Those to one side gave images having on the sides remote from the wire diverging lines indicating the repulsion of the accumulating electrons on the film by the wire above, and their repulsion for each other. The comparison of such shadow images with those made by light shining through the same holes showed differences of a very marked character.

Another interesting shadow picture made just before leaving home, was produced by replacing the pierced rubber plate by small fibers of glass, laid on the film at right angles to the wire above. These fibers were about half a millimeter in diameter. Some of them were hollow tubes and some were solid. The tubes gave shadows of uniform density. The solid fibers showed conclusive evidence of refraction. In every case the shadow image shows a sharp black line along its center, where the fiber made contact with the film.

Wood, of Johns Hopkins University, suggested that this might indicate the presence of high frequency ether waves, and suggested the use of red or yellow glass, with the other glass fibers.

On returning home Wood's suggestion was carried out. After many attempts two fibers of glass, the one of colorless and the other of red sealing in glass, each having the same diameter, were prepared. This diameter was 0.079 cm. The red glass gave a slightly less sharply defined focal line. There is little if any absorption. By pushing the exposure, diverging discharge lines were shown at either end of the block focal line. This gives unmistakable evidence of the action of negative electrons.

On using a red rod of diameter 0.420 cm. the shadow picture showed white along the line of contact with the film. The absorption was then complete.

FRANCIS E. NIPHER

SOCIETIES AND ACADEMIES

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

THE 422d regular meeting, on October 13, 1908, was addressed by Major Charles E. Woodruff, surgeon, U. S. A., on "Anthropological Studies on the Effects of Light."

Major Woodruff briefly reviewed the various advances which have been made in the study of the effect of light on organisms. He gave special attention to the value of light in the treatment of tuberculosis. It was thought, said Dr. Woodruff, that fresh air, good food and abundance of light, were the three most beneficial things in the treatment of this disease. He had reached the conclusion that the last factor was harmful, and that the success of certain cloudy regions was due to the lesser degree of light; and that brilliant deserts increased the mortality to an alarming extent.

The paper was discussed by Professor McGee, Dr. Hrdlička, Dr. Lamb and others.

THE 423d regular meeting, on November 10, 1908, was a memorial meeting for Professor Otis Tufton Mason, of the National Museum, whose death occurred on November 5. Appropriate remarks on his life and varied activities were made by Dr. Theodore Gill, Dr. F. W. True, Dr. Aleš Hrdlička, Mr. Charles K. Wead and several others. Dr. Hrdlička read from the autobiography which Professor Mason had prepared several months before his death.

At the 424th regular meeting, on November 24, 1908, Dr. Aleš Hrdlička gave a synopsis of the results of his investigations among the various

Indian tribes of the United States for the International Congress on Tuberculosis.

Doctor Hrdlička visited the Winnebago, the northern Sioux, the Quinaielt, the Hupa and the Mohave tribes. Among all these peoples, Dr. Hrdlička describes the conditions as most appalling, giving rise to the belief that in a few years these tribes will be wasted to small remnants. The housing, food and personal habits are of the most primitive character, and there seems to be an utter disregard of all rules for the prevention of the spread of tuberculosis. Perhaps the most alarming conditions were found among the virile Sioux, who are rapidly succumbing to this dread disease. He held that in most cases the ultimate cause of the ravages of consumption among the Indians is due to the adoption of clothing, houses, food, etc., of the whites, and the lack of knowledge as to the communicability of disease.

The results of Dr. Hrdlička's researches will be published in the forthcoming report of the International Congress on Tuberculosis.

At the 425th regular meeting, on December 22, 1908, Dr. J. W. Fewkes read a paper illustrated with lantern slides on the excavation and repair work at Casa Grande, done by the Smithsonian Institution during the past two winters. The prehistoric settlement, of which Casa Grande is the best preserved building, was found to include several rectangular walled enclosures (compounds) in an area of several acres. Five of these compounds were excavated and repaired. Views were shown of mounds before excavation and others illustrated bird's-eye views of the same in their present condition.

The character of the repair work, especially the means adopted to preserve the walls from the elements was described and illustrated.

At the 426th regular meeting, on January 5, 1909, the following program was presented:

"Expedition to Sian-Fu, China, to Procure a Replica of the Nestorian Tablet," by Mr. Fritz Von Holm.

This tablet is dated A.D. 781 and contains an inscription of about 2,000 Syriac characters giving the part of Asia from which this body of Christians had come, a list of the benefits conferred on them by the Chinese emperors and other matters of historical importance. It was discovered in modern times in 1625 and set upon a stone pedestal in the shape of a turtle, but although visited occasionally, little care was taken of it until 1907, when the interest excited by Mr. Von

Holm's journey induced the officials to remove it to the Peilin or "forest of tablets," where it will be protected from the weather and its life prolonged many years. Mr. Von Holm recounted the interesting details of his expedition, the various difficulties which beset his work and the final deposit of the replica in the Metropolitan Museum of Art in New York. The lecture was illustrated by about forty excellent lantern slides.

"Remarks on Nestorianism," by Dr. I. M. Casanowicz.

This address was largely in illustration of the paper preceding, and consisted in a brief review of the past history and present condition of the Nestorian sect. Unlike most Christian bodies, Nestorians were fostered by both Persians and Arabs, and at the zenith of their power under the latter the Catholicos, or supreme head of the Nestorian Church, had under him twenty-five metropolitans, each of whom in turn was over not less than five bishops. Nestorians penetrated to China, Ceylon and India, where they were found by the Portuguese and are known as Christians of St. Thomas. At the present time a portion of the Nestorians of southwestern Asia have united with Rome, while those who still maintain their independence, numbering about 70,000, have been the object of labors by Protestant missionaries from England and America.

At the 427th regular meeting, on January 19, 1909, Mr. Juul Dieserud presented a paper on "The Scope and Content of the Science of Anthropology." Mr. Dieserud was originally led to take up this problem in cataloguing scientific works, first at the Field Columbian Museum, Chicago, and later at the Library of Congress. His attitude was, therefore, that of the librarian and not of the working anthropologist, and was governed by a study of the attempted classifications of professional anthropologists as compared with the actual works requiring classification. It followed closely, though with elaboration in many points and condensation in others, the course of his argument in his book bearing the same title.

The paper was discussed at some length by Professor McGee, Dr. Fewkes, Dr. Swanton and Dr. Folkmar.

WALTER HOUGH,
Secretary

THE GEOLOGICAL SOCIETY OF WASHINGTON

At the 210th meeting of the society, held on Wednesday, November 25, under informal com-

munications, Mr. Ernest A. Shuster described briefly the original boundary stones of the District of Columbia.

Regular Program

The International Geographic Congress: Mr. DAVID T. DAY.

The Correlation of Sections Lithologically Similar: Mr. WILLIS T. LEE.

A geologic section of the coal-bearing rocks of the Grand Mesa coal field of central western Colorado, hitherto referred to the Mesaverde, was shown to be strikingly similar to the section, in the Raton coal field of New Mexico, of rocks hitherto referred to the Laramie. The evidence on which the correlations have been based is not conclusive and attention was called to the desirability of reexamining it in the light of new evidence. The recently discovered facts likely to influence the revision of correlations are: (1) a line of unconformity discovered a year ago (1907) in the Grand Mesa field separating the coal-bearing rocks into an upper and a lower member; (2) a similar line of unconformity discovered during the present season (1908) in the Raton field separating the coal-bearing rocks into two formations and (3) the stratigraphical evidence and fossil plants collected from both formations apparently indicate that the unconformity in the Raton field represents a period of erosion comparable to the post-Laramie erosion in the Denver basin.

Coon Butte or Meteor Crater: GEO. P. MERRILL.

The region of Coon Butte, near Canyon Diablo, is underlain by a light gray to buff Carboniferous (Aubrey) limestone some 200 feet in thickness, this by a light gray saccharoidal sandstone of not above 500 feet in thickness, and this, again, by a red-brown sandstone of undetermined thickness. These rocks lie nearly horizontally and are little disturbed.

The crater was described as roughly circular in outline and nearly 4,000 feet in diameter. The crater rim at its highest point is 100 feet above the level of the plain and the present bottom some 350 feet below. The rim is composed wholly of sharply upturned edges of the limestone, covered with fragments of the same, as well as fragments of the underlying sandstone, in sizes varying from microscopic to those weighing thousands of tons. Exteriorly the crater rim slopes gradually away to the plain. Interiorly the broken edges of the upturned limestone form steep,

and often perpendicular, walls. Borings made from the crater bottom vertically downward to a maximum depth of some 1,100 feet pass through a comparatively thin layer of lake bed material and talus (rarely 100 feet in thickness) into a zone of rock flour composed of the shattered granules of sandstone, and thence, at depths of about 650 feet below the crater bottom, into firm red-brown sandstone. No traces whatever were found of the ordinary volcanic products, as lava or scoria, excepting such small particles as had drifted from distant sources.

While not committing himself definitely to the theory of origin through impact of a gigantic meteorite, and while pointing out the seeming objections to such an hypothesis, the speaker showed that nevertheless no other conclusion seemed possible. Not merely had the borings in all cases reached a firm rock bottom, but the detritus thrown out, or now occupying the crater bottom, was wholly of the nature of the lime-and-sand stone (and its derivation products) forming the upper 800 feet of the strata.

The paper was illustrated by lantern slides.

At the 211th meeting of the society, held on December 9, 1908, Mr. F. E. Matthes presented the following paper: "The Glacial Character of the Yosemite Valley."

The glacial character of the Yosemite Valley is essentially a graded one—most pronounced at the upper end, gradually fading downvalleyward and ultimately vanishing at the lower end. This finds its explanation in the circumstance that the valley lay close to the periphery of the glaciated zone of the Sierra Nevada. Only the strongest glacial floods pushed any distance beyond the lower end of the valley. Most of the ice floods were of moderate volume and either barely reached its lower end or did not advance more than half way down the valley. The lower portion of the Yosemite has, therefore, been invaded by ice only at considerable intervals, and then by glacier ends mostly. Its glaciation has been feeble and stream erosion has ever had the upper hand in its fashioning. The upper half of the valley, on the contrary, has suffered frequent and relatively vigorous ice erosion and has consequently acquired a much more typical glacial aspect.

The gradation of the glacial character of the Yosemite is interrupted and obscured by a variety of aberrant sculptural features. These are explained by the selective action of the ice on rock-masses of widely different degrees of fissility.

The granites of the Yosemite region are noted for their extreme and abrupt structural variations; they range in character from the schistose to the massive. The ice work in the valley was consequently subject to the controlling and directive influences of these exceptionally diverse structures. Again, the relative potency of these structural controls was the more marked because of the moderate size and disrupting power of the ice masses involved.

At the close of Mr. Matthes's address the sixteenth annual meeting of the society was held for the purpose of electing officers, and the following officers were elected for the ensuing year:

President—Mr. George Otis Smith.

Vice-presidents—Mr. M. R. Campbell and Mr. T. W. Stanton.

Secretaries—Messrs. Philip S. Smith and F. E. Matthes.

Treasurer—Mr. C. A. Fisher.

Members at Large of the Council—W. C. Mendenhall, Geo. W. Stose, Geo. H. Ashley, E. S. Bastin, L. C. Graton.

RALPH ARNOLD,
Secretary

THE CHEMICAL SOCIETY OF WASHINGTON

THE 187th regular and 25th annual meeting of the Washington Chemical Society was held at the Cosmos Club, Thursday evening, January 14, 1909. President Walker presided, and the attendance was 80.

Two papers were read, viz.:

"Technical Analysis of Water," by R. B. Dole, of the Geological Survey.

"Prevention of Dust on Highways," by Prevost Hubbard, of the Division of Public Roads.

The report of the secretary showed that 84 new names had been added to, and 42 names removed from the list of members during the past year. The membership of the society is now over 230. A proposed amendment to the by-laws, changing the time and manner of holding the election of officers, was submitted. The election of officers resulted as follows:

President—P. H. Walker.

First Vice-president—G. H. Failyer.

Second Vice-president—W. W. Skinner.

Secretary—J. A. LeClerc.

Treasurer—F. P. Dewey.

Extra Members of the Executive Committee—H. C. P. Weber, M. X. Sullivan, H. E. Patten, H. C. Gore.

J. A. LECLERC,
Secretary

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE OPSONINS AND OTHER ANTIBODIES¹

LOOKING back, we find that only fifty years ago the conception of the nature of the processes that run their courses in the animal body in infectious diseases, generally speaking, were hazy and still often even mystical. Preceded by occasional brilliant anticipations, notably by Bretonneau in regard to the specificness of infectious processes and by Henle with respect to the interaction between parasite and host, the tireless, unmeasurably fruitful investigation of the modern era, introduced by Pasteur and Koch, has brought to light not only the actual causes of many infectious diseases, but a great deal also in regard to the means and reactions in the infected body whereby they are overcome. Of these defensive processes phagocytosis and the action and formation of that remarkable group of bodies known as antibodies have received and still receive the greatest amount of attention. Indeed, the discovery of the wonderful power of the animal organism to respond to the effects of certain substances by the production of new antibodies must be reckoned as one of the great events, not only in medicine, but in general biology. We feel best acquainted with the antitoxins, the lysins, the agglutinins, the precipitins and the opsonins, but this does not exhaust the list, which is a growing one. The estab-

¹Address of the vice-president and chairman of Section K—Physiology and Experimental Medicine, American Association for the Advancement of Science, Baltimore, 1908.

lishment of curative serum therapy by Behring when he demonstrated that antitoxic serum protects healthy animals against fatal doses of the corresponding toxin and may even cure the already sick, served to turn to the common good this innate faculty of the animal body to develop in so marvelous a manner its own resources.

Let it be noted once more that serum treatment, which has robbed diphtheria of its former terrors and the benefits of which are being extended to other diseases, is the direct outcome of scientific animal experimentation, and that without such experimentation it would not have been discovered and could not be maintained and extended.

The new methods and principles developed by the study of the animal reactions to infection did not long remain the exclusive property of the workshop of the bacteriologist. Ehrlich's side-chain theory of toxic and antitoxic action proved most heuristic, leading directly to fruitful investigation of other fields, and to-day biology, clinical and legal medicine, and physiological chemistry are using *immunological* methods to solve important problems.

According as stress was placed on the part of phagocytosis, on the one hand, and on the rôle of antibodies, antimicrobial as well as antitoxic, on the other hand, investigators until but recently were largely partisans of either the phagocytic or the humoral theory of healing and immunity. But the sharp antagonism between the adherents of these theories has subsided, because it has been made clear that neither mode of action is accomplished without the cooperation of cells and fluids. This is particularly true and easy of demonstration in the case of phagocytosis. Metchnikoff, the genial founder of the phagocytic theory, by broad comparative studies established the general occurrence and the

significance in health and disease of phagocytosis in the higher as well as in the lower animals, and Denys and others have shown that the fluids of the blood play an essential part in the phagocytic process by so acting on microbes and other elements that they are made susceptible of phagocytic action. This property of the blood-fluid is now ascribed to definite substances, the opsonins of Wright and Douglas, and the tropins of Neufeld, both in all probability the same substances, and destined, I believe, to bear the name of opsonins, at least in the English language. While our acquaintance with the opsonins dates back only four or five years, they have been the subject of many researches, and much has been written about them, and it is to some more or less final results and certain general bearings of this work, fruit of the phagocytic theory as modified and perfected by the opsonic theory, that I wish to direct your attention.

It is generally accepted that phagocytosis of many bacteria—and also of red blood corpuscles, which are highly serviceable objects for the study of certain problems—is dependent upon substances—opsonins—which become attached to the bacterial cells or corpuscles, as the case may be, and so alter them that they are readily taken up by the leukocytes. The chief reasons for this conclusion are that leukocytes, carefully freed by repeated washing in salt solution, from the fluids in which they naturally exist, have but very little or no phagocytic power with respect to certain bacteria or corpuscles suspended in salt solution, while the same bacteria or corpuscles, after having been treated with suitable opsonic serum and then freed from the serum, are taken up by serum-free leukocytes. A few bacteria, however, *e. g.*, influenza bacilli, are readily phagocytatable without the presence of opsonic serum.

Bacteria or corpuscles are not necessarily altered in opsonic serum and many bacteria, notably streptococci, pneumococci, anthrax bacilli, as well as others, grow freely in such serum. Heretofore the belief that phagocytes may cause destruction of bacteria rested largely upon more or less convincing morphological appearances. By means of the plate method for demonstrating bactericidal action it now has been shown conclusively that certain bacteria that do not suffer demonstrable injury by blood serum alone, such as those just mentioned, undergo intraphagocytic destruction when put into mixtures containing living leukocytes and opsonically active serum. In serum alone and in suspensions of serum-free leukocytes active growth occurs, but when the two are mixed destruction takes place, other factors being equal, in proportion to the number of leukocytes present. The actual demonstration of phagocytic annihilation of bacteria, formerly so often demanded by the opponents of the phagocytic theory, is here furnished.

The indications are that various opsonins with more or less well-marked specific affinities occur in all animals down to and including the echinoderms, being, like other antibodies, present to a variable extent in normal blood and other fluids.

In the course of his studies on lymph formation Professor Carlson² finds that opsonins and related bodies are more concentrated in the serum than in the lymph, that their concentration varies in the lymph from different organs, and that their apparent relative concentration in different lymphs also varies. The fact that the relative concentration is not the same in all lymphs speaks of course strongly in favor of the antibodies being distinct substances, a point concerning which there is still difference of opinion,

² Personal communication.

some believing that it concerns different modes of action of the same body, others that each action is dependent upon a distinct body.

At first opsonins were regarded as substances of a relatively simple structure, quite easily destroyed by heat (60° C. for 15 to 30 minutes) and other agents. But it has been found that in most cases the total opsonic effect of fresh serum is the result of the combined action of two bodies, one relatively resistant to heat, the other easily destroyed by heat. The heat-resistant element is capable of opsonic action by itself and seems to unite quite firmly with the object upon which it acts; the opsonic effect as measured by the resulting phagocytosis is, however, greatly promoted on the addition of the other, thermolabile element, which alone has no opsonic power. In other words, opsonins, as a rule, seem to have the same duplex constitution as the lysins with which they are held by some to be identical.

The heat-resistant opsonic element appears to attach itself firmly to the bacterium or corpuscles upon which it acts because, in some instances at least, it is not detached even after many washings of the opsonified bacteria or corpuscle in large quantities of salt solution. Consequently opsonification is to be regarded as the special action of a distinct unit and not as the result of the influence of plasma or serum as a whole. The thermolabile, activating element, however, according to the results of recent experiments, probably remains free in the fluid of the phagocytic mixture, and there seems to me to be good room still for question as to whether its effect is exercised upon the phagocytizable object or upon the phagocyte. Years ago Metchnikoff expressed the view that serum may stimulate leukocytes and other cells directly to phagocytosis, while, on the other hand, bacteria or red blood corpuscles that

take up what he and his followers then called "fixateur" thereby are made phagocytatable. It is not impossible that further analysis of the mechanism of phagocytosis, under the guidance of the opsonic theory, will lead to this as the final result. At all events the failure to recognize the interaction of the two elements in the opsonic function of serum and the great difference in their combining properties is responsible for many of the divergent results of various investigators.

While normal blood contains only comparatively small amounts of heat-resistant opsonic substances, each unquestionably possessed of more or less well-marked specific affinities, the blood in conditions of acquired immunity may be richly charged with newly formed thermostable opsonic substances with marked specific affinity for the object against which the immunity is directed. Injections of suitable animals with bacteria or with alien red corpuscles cause specific opsonins to form; in human beings new opsonins arise as the result either of spontaneous infections or of the artificial introduction of killed bacteria and various bacterial products.

The opsonin content of the blood may be measured more or less accurately, either by means of the opsonic index or by determination of the highest dilution of the serum at which opsonic effect is still obtainable and comparing it with some normal standard. Speaking only in general terms, the opsonic index of Wright with respect to a given bacterium is obtained by comparing the number of bacteria taken up under the influence of the serum of the person or animal in question with the number taken up under the influence of the corresponding standard of normal serum under conditions that are as comparable as they possibly can be made.

By following the fluctuations of the op-

sonin content at frequent intervals important facts have been learned in regard to the laws of opsonin production. In the language of immunology any substance capable of giving rise to antibodies in suitable animals is called an antigen. Microbes and various microbial derivatives, cells, red corpuscles and serum may contain several antigens and incite the formation of more than one kind of antibody so far as indicated by the usual modes of antibody effect. Thus the proper single injection in a suitable animal of typhoid bacilli or of alien red cells is followed usually by the appearance in the blood of increased amounts of lysins (lytic amboceptors), agglutinins and opsonins for the particular cells injected. Usually all three of the bodies mentioned are not increased in the same proportions so far as determinable by our present methods of measurement, but they all commonly follow the same general course, which seems to hold good for antibodies in general: For the first day or two or three there is often, but apparently not always, a fall below normal in the amount of the specific antibodies in the serum; this period is called the negative phase and is succeeded by a steady rise above the normal, which, as a general rule, reaches its maximum about the eighth to twelfth day when there is a fall, the apex of the curve being sometimes quite sharp, at other times more rounded, and then begins a gradual return to the normal.

It is important to note that the fall below normal, the negative phase, is specific, that is, affects only the normal opsonin, and by inference the other antibodies, for the particular bacterium or corpuscles injected, a clear indication, it strikes me, that there are several normal antibodies, each with specific affinities and probably not different from the corresponding body formed when the machinery of immuniza-

tion is set in motion. The cause of this interesting negative phase is not well understood, but it lies closely at hand to ascribe it to neutralization of the normal antibodies by the antigen, or to its effect on the antibody-forming cells. There is good reason to believe, especially on clinical grounds, that the general resistance to the specific infection is lowered in the negative phase, although certain experimental results indicate that the opposite may be the case.

Blood serum may contain antigens causing the production of antibodies for its homologous corpuscles; thus, the injection of antidiphtheric horse serum is followed by a wave-like rise and fall of the lysin, agglutinin and opsonin for horse corpuscles in the blood of the patient, the highest point being reached usually about the tenth day. Undoubtedly these antigenic substances are derived from disintegration of the corpuscles.

Serum and other protein mixtures also induce the formation of specific precipitating substances in suitable animals. Whether the specific precipitin test for protein material, now extensively used for the identification of blood and in the solution of allied problems, will prove of service also in the study of pure proteins, remains to be seen.

In several acute infectious diseases the course of the formation of new opsonin for the infecting agent, in the typical attack, terminating promptly in recovery without complications, shows a marked general resemblance to the opsonin or antibody curve after a single antigen injection in the normal animal. It also bears definite and constant relations to the clinical phenomena. During the early stages when the symptoms are pronounced there is a negative phase, and then as the symptoms begin to subside the opsonin curve rises above normal, reaching the

highest point several days after the onset, followed by a gradual subsidence. This is true of the pneumococcus opsonin in pneumonia, of the opsonin for the diphtheria bacillus in diphtheria, of the streptococcus opsonin in erysipelas, and also of the opsonin for the diplococcus of mumps in that disease. The curve is typical as well for the streptococcus in scarlet fever, indicating clearly that this organism unquestionably plays a definite rôle in scarlet fever whatever its actual causative relation to the disease may be. In pneumonia the greatest rise in the leukocytosis appears to precede somewhat the highest rise of the opsonin. In all these diseases the typical wave-like opsonin curve is modified by the development of complications of various kinds and at the onset of which it commonly undergoes a distinct depression. In rapidly fatal cases, for instance of pneumonia, the opsonic curve or index may not return from the primary depression but sink lower and lower. In prolonged infections, general as well as local, there occur irregular fluctuations and in chronic, more or less stationary cases, the opsonic index is often subnormal. At this time further details can not be given. My chief point is to make clear the close association between recovery and the wave-like rise of the opsonin and, as a result of the immunization, in all likelihood also of other antibodies in the typical attack of acute so-called self-limited infections. In some of the diseases the opsonin is the only antibody that we can measure readily with our present means. As I have stated, intraphagocytic destruction of pneumococci and streptococci takes place in the presence of fresh leukocytes and opsonic serum, whereas either alone constitutes a good medium for these bacteria. Taking these facts into account, it seems to me that the wave-like course of the opsonin in pneumonia and in acute streptococcus infec-

tions is a strong point on the side of the importance of phagocytosis in their healing, whatever other measures, of which at present we know less or nothing, may be in operation also.

Whether the opsonic action of serum is caused by distinct and independent substances or by antibodies with other actions as well, has been an interesting question concerning which there is still difference of opinion. The question now seems to be narrowed down to whether the opsonins and lysins are the same, some claiming that opsonification merely is the result of an early stage of lysis before actual solution takes place. Opsonins would appear to be distinct from other antibodies because a given serum may be opsonic, but not lytic, while the reverse probably also occurs. But here certain difficulties arise. While it is well established that serum may be strongly opsonic without being lytic and without even containing lytic amboceptor so far as our present methods indicate, the suggestion is made that in such cases the failure to obtain lysis may be owing to the state of the object tested and not to the absence of lysins. This consideration applies with most effect to instances in which we know the bacterium or corpuscle is susceptible both to lysis and to opsonification, and in which lysis might not take place either because the serum was not active enough or because of some special resistance to lysis. The explanation falls short, however, when applied to bacteria like pneumococci and streptococci, which, while readily opsonified, are yet insusceptible to lysis. In this case the claim that lysis does not take place because of the physical state of the bacteria is merely an assumption.

If opsonification and lysis depend upon the same body the opsonic and lytic powers of the serum of an animal in the course of immunization should always run parallel.

If they do so that fact does not of itself prove that it concerns one body, but failure to run parallel would indicate the existence of separate bodies with different functions. Actual observations show that in certain animals single injections of alien red corpuscles may increase the opsonic power of the serum for that corpuscle a hundred times or more above normal, while the lytic power for the same corpuscle may be increased comparatively much less and in some conditions not at all. On this account, then, as well as for other reasons, the view that opsonins, meaning thereby the thermostable opsonic substances, constitute a distinct class of antibodies, seems to me to be correct.

That the activating or complementing opsonic substance is closely related to the complement of lysis is indicated by a number of considerations: Both are sensitive to the action of heat, being destroyed by an exposure of thirty minutes to 58-60° C.; both appear to be split up into two distinct components by water, and both are neutralized by a number of ionizable salts. As stated before, the opsonic complement, however, seems to remain free in the phagocytic mixtures, whereas the complement of lysis is regarded generally as bound by the amboceptor.

We come now to a most interesting part of our subject, namely, the resistance offered by microbes under different conditions to antibodies and more particularly to opsonins.

Since the discovery of the chronic microbe carrier the adaptation of microbes to the defensive mechanisms of the animal body is no longer merely of academic interest. Under the conception that phagocytosis and bacteriolysis form the basis of healing and immunity in perhaps most of the infectious diseases, the infecting microbes should disappear at the time of recovery. This is probably the general rule,

but there are many striking exceptions illustrated well by the now familiar "*bacillus carrier*." The body may overcome the disease but not the cause, which may persist in spite of the increase in antibodies. The disease subsides, the disturbances are smoothed away, and yet the germ lives on in the host, apparently harmless and unharmed, sometimes for remarkably long periods. But the equilibrium is not always a stable one; the immunity of the host may give way and recurrence develop; or the resistance of the germ may weaken and eventually complete destruction and final elimination take place.

Germ isolated from typhoid and cholera carriers have been found in some cases to offer special resistance to antibodies, including opsonins, but the mechanisms of this mutual immunization of microbe and host are still obscure, and on account of the self-evident and tremendous importance of the carrier in spreading disease they invite special study.

At this point I may recall that the relapses in relapsing and related fevers are now ascribed to the survival in each attack of a few spirilla which, having become immune to the antibodies of the host, give origin to new "serum-fast" strains that continue the relapses.

Exceedingly interesting conditions are found in certain chronic infections of the urinary tract with bacilli of the colon group, the indications being that the infecting bacillus may partially immunize itself, in one case to the lysin, in another to the opsonin, in the patient's blood, or that the amounts of different antibodies vary greatly in the different cases.

In Metchnikoff's original doctrine of phagocytosis in infectious diseases a fundamental tenet reads that as a microbe grows in virulence its resistance to phagocytosis increases. Recent experiments give results in complete harmony with this

teaching. On analysis the resistance of certain highly virulent bacteria to phagocytosis is found to depend on insusceptibility to opsonic action, owing apparently to lack of affinity for the opsonin. As pneumococci, streptococci and other bacteria on successive passages through suitable animals become more and more virulent for these animals, they at the same time acquire a parallel increase in resistance to phagocytosis. When cultivated outside the body reversion readily takes place to less virulent states, associated with a returning affinity for opsonin and an increasing susceptibility to opsonic action. Investigating this property of pneumococci to develop such strong defense against phagocytosis, Rosenow found that extraction or autolysis of virulent pneumococci brings into solution a substance or group of substances that neutralize the pneumococco-opsonin in human serum, but not other opsonins. After extraction of this substance, which is thermostable and insoluble in alcohol or ether, virulent pneumococci unite with opsonin and become phagocytatable, while avirulent pneumococci on treatment with extracts of virulent strains not only become resistant to phagocytosis in the test-tube, but also to some degree virulent for animals.

Entirely independently, Tschistovitch and Yourevitch appear to have reached identical results on all points, except that they did not study the virulence of avirulent pneumococci after treatment with extracts of virulent strains.

We may say then that the properties called *virulence* in pneumococci appear to depend, to a very large extent, if not wholly, on the formation of an actual substance—"virulin"^a—which may be extracted and studied by itself. It is hoped that this demonstration may prove a basis

^a "Antiphagin"—Tschistovitch and Yourevitch.

of departure for new and fruitful work in pneumococcus and similar infections.

*THE FIRST ANNUAL CONFERENCE OF THE
GOVERNORS IN NEW ENGLAND*

IN these days of conventions and association gatherings, it is difficult to select one on the grounds of special importance or significance. Among those which I have had the privilege of attending in recent years, the conference held in Boston, November 23 and 24, easily surpassed all others of material import when measured by the importance of the subjects considered and the vast possibility of bettering existing conditions. This was the first annual conference of the Governors of the New England states, called for the purpose of considering certain natural industries and utilities common to all, and legislation affecting them.

The conference was presided over by Governor Curtis Guild, Jr., of Massachusetts, and attended by every governor in office and governor-elect with one exception, namely, Governor Higgins, of Connecticut, "who had married a wife and therefore could not come."

Subjects Considered.—There were three sessions, and each session was devoted to the consideration of one subject, or a correlated group of subjects. The first session was devoted to tree planting interests, and this was divided into two parts: (1) Forest trees and (2) orchard trees.

The forest-tree side was discussed by Mr. Gifford Pinchot, United States forester, who showed impressively how rapidly the forest supplies of the country were decreasing; how vast areas of lands in New England, of little or no value for farming, might be utilized; the profitableness of forests as a commercial enterprise; and then finally urged the passage of uniform legislation in New England providing adequate protection of forest lands against fires. This subject aroused a lively discussion, and drew attention to the reason-

able opportunities for safe investment of capital.

Orchard Trees.—The planting of apple trees on the hilly lands in New England, not in the valley farming lands, was urged by the professor of horticulture of Cornell University. He did this on the ground that New England was the natural home of the apple in the United States, for it was here that the leading commercial varieties of to-day originated; that the land was cheap, that labor was abundant, and markets both foreign and domestic convenient. Moreover, the quality of the New England apple was unsurpassed by that produced in any other section. The demand was keen, and for fruit of fine quality New England markets were the best in the country.

What was needed to improve the situation was reorganization of ideas and practices in relation to orcharding. The slipshod methods of generations and the opening of new irrigated fruit lands in the west discouraged on the one hand the would-be planter, and on the other attracted his attention to the opportunities in distant lands. What in his opinion was now needed was the redirection of capital to apple-growing as a staple and safe industry. We should have illustration orchards, planted and conducted either by men of faith in the business with sufficient capital to back up the enterprise, or by the state governments themselves. Such work should be conducted with the energy characterizing western enterprises, and guided by intelligence and up-to-date methods. Certain legislation was required in order to secure a uniform grade, uniform methods of packing, and certain standard packages.

The second session of the conference was devoted to a consideration of the fast-disappearing lobster and the much-preyed-upon mollusks.

These subjects were discussed by experts and aroused much interest. They proved their contention that these staple sea foods were in a fair way to be exterminated within a measurable length of time, and that without intelligent protection a great natural re-

source of most of the New England states would disappear.

Highways.—The highway problem, of course, aroused an interesting discussion, for here the advocates of the purely utilitarian met the devotees of pleasure on a common ground. Methods of constructing highways, the repair of highways and the influence of the automobile on the life of the highway, were live issues of this general topic. The necessity of constructing trunk lines whereby the leading centers of New England should be directly connected, and the necessity of providing for adequate maintenance, suggested the desirability of cooperation in the prosecution of these purely interstate projects.

The conference was made up then of these three sessions, crowded full of features of interest. In addition to the eleven governors, a number of invited delegates representing the topics mentioned above were present, and were allowed the courtesy of the floor for their periods.

Mr. F. L. Dean, secretary to Governor Guild, acted as executive secretary of the conference and will have charge of printing the report of the proceedings.

A feature of the conference was the masterly, and one might say artistic, way in which the speakers were introduced and the discussion expanded, or repressed as occasion seemed to demand, by the versatile chairman, Governor Guild, of Massachusetts. Undoubtedly the first of a great series of conferences, whereby questions of common import to the New England states shall be considered impartially and uncolored by political surroundings, has been launched, and unquestionably it will be followed by others even more influential in character.

JOHN CRAIG

DR. GIUSEPPE NOBILI

PROFESSOR LORENZO CAMERANO in the *Bollettino dei Musei di Zoologia ed Anatomia comparata della R. Università di Torino*, Vol. XXIII., number 595, announces the death of Dr. Giuseppe Nobili on the fourth of December, 1908, at Omegna, Italy. He was the

son of Dr. Gaudenzio and Adele Antonioli Nobili and was born at Omegna, February 11, 1877. He received his doctor's degree in natural science at the Royal University of Turin in 1899, becoming also an assistant in the Zoological Museum of that University, and later (1903) was made an assistant in the Museum of Comparative Anatomy.

While a student at the university he engaged in some botanical researches and published several interesting notes. He soon, however, turned his attention to zoology and as early as 1896 wrote a paper on the decapod crustaceans collected by Dr. A. Borelli in the Argentine Republic and Paraguay. This was the first of a long series of publications chiefly on Crustacea (Decapoda, Stomatopoda, Isopoda, etc.) based on collections in the museum at Turin, and also in those at Geneva, Genoa, Naples, Paris, Budapest and Madrid. These papers (53 titles in all) contain descriptions of many new genera and species and critical discussions of others, and form an important contribution to our knowledge of the Crustacea. Foremost among them is his monographic work on the decapods and stomatopods of the Red Sea, published in the *Annales des Sciences Naturelles* (9), IV., 1906. Professor Camerano pays a high tribute to the personal character of Dr. Nobili, who, by his unwearying activity, had built up the collections in the Turin Museum, and by his kindness of heart had won the affection and esteem of his associates.

DARWIN ANNIVERSARY ADDRESSES AT THE UNIVERSITY OF CHICAGO

THE Biological Club of the University of Chicago has arranged the following program:

February 1—Introductory remarks by President H. P. Judson.

"The World's Debt to Darwin," Professor E. G. Conklin, Princeton University.

February 2—"The World of Thought Before and After the Publication of the Origin of Species," Professor G. H. Mead.

February 4—"Cosmic Evolution," Professor F. R. Moulton.

February 9—"Bridging the Gap between Living and Lifeless," Professor A. P. Mathews.

February 10—"Phylogeny," Professor S. W. Williston.

February 17—"Variation and Heredity," Professor W. L. Tower.

February 18—"The Interpretation of Environment," Professor H. C. Cowles.

February 24—"Darwinism and Political Science," Professor C. E. Merriam.

February 25—"Human Evolution—Physical and Social," Dr. Geo. A. Dorsey.

March 3—"The Influence of Darwinism on Psychology," Professor J. R. Angell.

March 4—"The Theory of Individual Development," Professor F. R. Lillie.

March 10—"The Evolution of Religion," Professor Shailer Mathews.

March 11—"Darwinism and Experimental Methods in Botany," Professor D. T. MacDougal, Carnegie Institute.

March 17—"Evolution in Language and in the Study of Language," Professor C. D. Buck.

March 18—"Selection Mutation and Orthogenesis," Professor C. O. Whitman.

SCIENTIFIC NOTES AND NEWS

DR. JAMES B. ANGELL proposes to present his resignation as president of the University of Michigan on February 17. It is understood that the office of chancellor will be created and that he will be the first to occupy this position.

DR. WILHELM TRABERT, professor of cosmical physics at Innsbruck, has been appointed director of the Austrian Bureau of meteorology and geodynamics, vacant by the death of Professor Penner.

DR. FRANK WIGGLESWORTH CLARKE, chemist, U. S. Geological Survey, and professor of mineral chemistry in the George Washington University, has been invited by the Chemical Society of London to deliver a memorial lecture on Dr. Wolcott Gibbs. As Professor Clarke is to attend the International Congress of Applied Chemistry, which meets in London on May 27, this lecture will follow shortly after the adjournment of the congress.

THE Academy of Natural Sciences of Philadelphia has elected as correspondents the following: Dr. Albert Calmette, of Lille; Dr. Sven Hedin, of Stockholm; Dr. Robert F.

Scharff, of Dublin, and Dr. John M. Clarke, of Albany.

SIR JAMES DEWAR and Dr. Ludwig Mond have been elected honorary members of the German Chemical Society.

M. P. VILLARD has been elected a member of the Paris Academy of Sciences in the Section of Physics to succeed M. Mascart.

ON the recommendation of a committee of the Royal Society of Arts and the Royal College of Physicians, the Swiney prize, of the value of \$1,000, has been awarded to Dr. C. A. Mercier, for his work on "Criminal Responsibility."

A NEW portrait of President Eliot, of Harvard University, by Mr. Charles Hopkinson has been hung in the Harvard Union, where it will remain for the next few days. The portrait represents President Eliot seated at his desk.

MR. H. F. NEWALL, assistant director of the Observatory, Cambridge, has been elected a fellow of Trinity College.

WE regret to learn that the illness of Professor G. D. Louderback, of the department of geology of the University of California, has made it necessary for him to take an indefinite leave of absence.

PROFESSOR F. W. BLACKMAR, head of the department of sociology in the University of Kansas, who has spent four summers in investigating the chief irrigating plants in western states, has finished a report on the development of irrigation and the reclamation service of the government in the arid west. This report will be published by the Carnegie Institution of Washington.

PROFESSOR TREVOR KINCAID, of the department of zoology, University of Washington, will leave Seattle about the first of April for Simferopol, Crimea, Russia, where he will undertake, for the U. S. Bureau of Entomology, the collection and shipment of parasites of the Gypsy moth. During the absence of Professor Kincaid, Professor A. D. Howard, Ph.D. (Harvard), formerly of Westminster College, Pennsylvania, will have charge of the department.

MR. L. F. NOBLE, graduate student in geology at Yale University, has returned from a six-months' trip in the Lower Colorado Canyon, where he has been pursuing studies in structural geology, particularly with reference to the Algonkian.

Nature states that Professor E. A. Minchin has left England for three months, accompanied by his assistant, Dr. Woodcock, on a visit to the zoological station at Rovigno, in order to carry on researches on the development of the trypanosome of the little owl (*Athene noctua*).

DR. CHARLES WILLIAM ANDREWS, F.R.S., assistant in the Geological Department of the Natural History Museum, London, has returned from Christmas Island, in the Indian Ocean, where he has been making scientific researches.

DR. SVEN HEDIN delivered at Stockholm on January 22 a lecture upon his travels in Central Asia before a large audience, which included King Gustav and the royal family, and the members of the Anthropological and Geographical Societies. The Wahlburg medal of the latter society has been conferred on Dr. Sven Hedin, and the society has raised a fund of over \$2,500 to be known by the explorer's name, which will be devoted to geographical research.

PROFESSOR A. G. WEBSTER, of the department of physics at Clark University, is giving three lectures under the auspices of the Sigma Xi Society at each of the universities of Missouri, Kansas, Nebraska and Iowa, and one each at Wisconsin and Northwestern, speaking on the present outlook in physics and on his researches in acoustics.

DR. R. S. WOODWARD, president of the Carnegie Institution of Washington, lectured to the students of the University of Wisconsin on the evening of February 2 on the work of that institution.

DR. WM. A. NOYES, professor of chemistry in the University of Illinois and editor of the *Journal of the American Chemical Society*, delivered an address before the Saint Louis Chemical Society, on January 29, on "La-

voisier." After the meeting an informal dinner was held in honor of the speaker.

PROFESSOR WM. J. GIES, of the department of biological chemistry of Columbia University, is conducting a course of public lectures on "The Chemistry of Digestion" on Monday evenings at Cooper Union. The lectures are illustrated by zoetrope figures, and by chemical and digestive demonstrations.

SIGMA XI lectures at the University of California have been given as follows: "The Effect of Solutions on Plant Growth," by Professor W. J. V. Osterhout; "Some Recent Discoveries in Solar Physics," by Professor E. P. Lewis; "The Origin and Distribution of Shell Mounds in the San Francisco Bay Region," by Mr. N. C. Nelson.

At the meeting of the American Nature-study Society held at Baltimore the following officers were elected for 1909: *President*, Professor C. F. Hodge, of Clark University, Worcester, Mass. *Vice-presidents*—Professor V. L. Kellogg, of Stanford University, Cal.; Professor F. L. Stevens, North Carolina College of Agriculture and Mechanic Arts, Raleigh, N. C.; Professor W. Lochhead, Macdonald College, Quebec; Professor O. W. Caldwell, The University of Chicago; Professor B. M. Davis, Miami University, Oxford, O. *Directors* (for two years)—G. H. Trafton, Public Schools, Passaic, N. J.; Professor F. L. Holtz, Brooklyn Training School, N. Y.; Professor J. Dearness, Normal School, London, Canada; Mrs. Anna Botsford Comstock, Cornell University, Ithaca, N. Y., and Dr. Ruth Marshall, Milwaukee High Schools. *Directors* D. J. Crosby, C. R. Mann, S. Coulter, H. W. Fairbanks and M. F. Guyer and Secretary M. A. Bigelow were elected in 1908 to serve two years.

A SCIENCE CLUB has been organized among the members of the agricultural department of Delaware College and the Agricultural Experiment Station staff. The following officers were elected: *President*, Professor C. A. McCue; *Vice-president*, Professor C. O. Houghton; *Secretary*, Professor A. E. Grantham. Weekly meetings will be held.

THE executive council of the British Science Guild has considered the matter of naming London streets after distinguished men of science. The members of the executive committee were requested to send in names which were reduced to the following thirty-one: Newton, Darwin, Harvey, Jenner, Huxley, James Watt, Gilbert, Kelvin, Faraday, Joule, Clerk Maxwell, Stokes, Tyndall, Captain Cook, Livingstone, Franklin, Ross, Bruce, Mungo Park, Cavendish, Dalton, Priestley, Boyle, Andrews, Halley, Herschel, Horrocks, Adams, Bradley, Howard, Piddington.

At the meeting of the American Philosophical Society, on February 5, Professor E. G. Conklin, of Princeton University, offered a minute in commemoration of the centenary of the birth of Charles Darwin.

THE Botanical Society of Pennsylvania has arranged a special meeting to commemorate the one hundredth anniversary of Darwin's birth and the fiftieth anniversary of the publication of the "Origin of Species." This will be held on Friday evening, February 12, in Biological Hall, University of Pennsylvania. The program consists of "A Short Sketch of Darwin's Life," by Dr. Henry Leffman; "Pre-Darwinian Theories of Plant Life," by Dr. Louis Krautter; "Darwin's Contribution to Botany," by Dr. J. W. Harschberger; and "Present Day Views on Organic Evolution," by Dr. C. H. Shaw.

THE deaths are announced of Dr. Hermann Minkowski, professor of mathematics at Göttingen, and Dr. Otto Rupp, professor of geometry at Brünn.

THE U. S. Civil Service Commission announces an examination on February 24, to fill a vacancy in the position of scientific assistant, \$720 per annum, in the Bureau of Fisheries, and vacancies requiring similar qualifications as they may occur.

THE next meeting of the Physical Society will be held at Columbia University, New York, on Saturday, February 27.

PROFESSOR W. A. SETCHELL has made a gift to the University of California of his herbarium, consisting of 15,468 specimens of algae.

NUMEROUS requests are received by the Geological Survey from educators, publishers and lecturers for photographs and lantern slides, in most cases those desiring them being willing to defray the expense of making the prints or slides, but there is at present no provision of law under which they can be furnished by sale. Some of these views taken by members of the survey have been used in a limited way by the survey in its publications; but many of these are out of print, leaving the photographic negatives to a large extent an unused resource of the public—data belonging to the public, but not available to it. If response could be made by the survey to the demands for prints from such negatives it would be in the interest of education and the dissemination of knowledge; and the survey being willing to supply reproductions from its great collection of photographic material, Senator Flint, of California, has introduced a proposed amendment to the civil service bill which reads as follows:

That the director of the Geological Survey shall hereafter furnish to any person, concern, or institution, in the interest of education and the dissemination of knowledge, that shall pay in advance the whole cost of material and services thereof, copies of any photographs or lantern slides in the possession of the United States Geological Survey; and the moneys received by the director for the same shall be deposited in the United States Treasury to the credit of the appropriation "Geological maps of the United States" of the said Geological Survey, and this provision shall become effective immediately.

A BILL to establish a bureau in the Department of the Interior to be known as the Children's Bureau, has been introduced in the House of Representatives. It reads as follows:

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That there shall be established in the Department of the Interior a bureau to be known as the Children's Bureau.

SEC. 2. That the said bureau shall be under the direction of a chief, to be appointed by the President, by and with the advice and consent of the Senate, and who shall receive an annual compensation of five thousand dollars. The said bureau shall investigate and report upon all mat-

ters pertaining to the welfare of children and child life, and shall especially investigate the questions of infant mortality, the birth rate, physical degeneracy, orphanage, juvenile delinquency and juvenile courts, desertion and illegitimacy, dangerous occupations, accidents and diseases of children of the working classes, employment, legislation affecting children in the several states and territories, and such other facts as have a bearing upon the health, efficiency, character and training of children. The chief of said bureau shall, from time to time, publish the results of these investigations.

SEC. 3. That there shall be in said bureau, until otherwise provided for by law, an assistant chief, to be appointed by the Secretary of the Interior, who shall receive an annual compensation of three thousand dollars; one private secretary to the chief of the bureau, who shall receive an annual compensation of one thousand five hundred dollars; a chief clerk, who shall receive an annual compensation of two thousand dollars; one statistical expert, at two thousand dollars; four clerks of class four; four clerks of class three; two clerks of class two, and six clerks of class one; five clerks, at one thousand dollars each; two copyists, at nine hundred dollars each; one messenger, at seven hundred and twenty dollars; two special agents, at one thousand four hundred dollars each, and two special agents, at one thousand two hundred dollars each.

SEC. 4. That the Secretary of the Interior is hereby directed to furnish sufficient quarters for the work of this bureau at an annual rental not to exceed two thousand dollars.

SEC. 5. That this act shall take effect and be in force from and after its passage.

COLUMBIA UNIVERSITY has arranged a series of free public lectures on Sanitary Science and Public Health which will be given in the large lecture room of the College of Physicians and Surgeons, No. 437 West 59th Street, on Mondays and Wednesdays during February, March and April. They will begin each day at 5 P.M., and the doors will be closed ten minutes later. The first lecture, "The Rise and Significance of the Public Health Movement," by William Thompson Sedgwick, professor of biology at the Massachusetts Institute of Technology, was given on February 1. Among the other lecturers and their subjects will be Professor Adami, of McGill Uni-

versity, "The Great Pathological Discoveries and their Bearing upon Public Health Problems"; Professor Burr, of Columbia University, "Water Supplies and Sewage Disposal"; "Public Health Problems of the Municipality, State and Nation," by Thomas Darlington, Health Commissioner of this city; Walter Bense, Sanitary Superintendent; Eugene H. Porter, State Health Commissioner, and Walter Wyman, Surgeon General, Public Health and Marine Hospital Service of the United States; H. M. Biggs, Chief Medical Officer of the New York Health Department, on "The Prevention of Tuberculosis," and Professor Theobald Smith, on "Diseases of Animals Transmissible to Man."

THE Cancer Commission of Harvard University announces a course of lectures on "Tumors," to be given on Thursday afternoons, at 5 o'clock, in the medical school. The lectures will be open to members of the university and to physicians. The dates and titles follow:

February 4—"The Bearing of the Experimental Investigation of Tumors on the Tumor Problem in General," by Dr. E. E. Tyzzer, Boston.

February 11—"The Regulatory Processes of Tumor Cells," by Dr. W. T. Howard, Cleveland, O.

February 18—"The Classification of Tumors," by F. B. Mallory, Boston.

February 25—"The Physiological Pathology of Intracranial Tumors," by Dr. Harvey Cushing, Baltimore, Md.

March 4—"The Etiology of Tumors considered from our Knowledge of Congenital Tumors and Tumors following Repeated Injury," by Dr. S. B. Wolbach, Albany, N. Y.

March 11—"The Problem of Cancer considered from the Standpoint of Immunity," by Dr. F. P. Gay, Boston.

PROFESSOR W. W. CAMPBELL, director of the Lick Observatory, writes that Volume VIII. of the publications of the observatory, now issuing from the bindery of the State Printing Office, Sacramento, contains heliogravure reproductions of the late Director Keeler's photographs of nebulae and star clusters made with the Crossley reflector. Other contents are a description of the Crossley reflecting telescope by Director Keeler, a list of the nebulae and clusters photographed, a catalogue of 744 new

nebulae discovered on the negatives, and new determinations of the positions of the nebulae previously known in the regions of the sky covered. It is hoped that the regular correspondents of the Lick Observatory can be supplied promptly with copies. The cost of the volume has been unusually high on account of the expensive processes and materials employed. There are 71 full-page heliogravure reproductions, printed by hand press on suitable paper.

THE Cleveland Chemical Society has organized itself into a local section of the American Chemical Society with the following officers: *President*, Franklin T. Jones; *Secretary*, Sherley P. Newton; *Board of Managers*, H. V. Army, W. R. Veazey, president and secretary *ex-officio*; *Councilor*, C. F. Mabery. A charter has also been granted for the formation of a section of the American Chemical Society comprising the western portion of the state of Washington with headquarters at Seattle.

At the recent meeting of the Southern Society for Philosophy and Psychology, held at the Johns Hopkins University, Baltimore, Md., the following officers were elected for 1909: *President*, Professor Albert Lefevre, University of Virginia; *Vice-president*, Dr. Shepherd Ivory Franz, Government Hospital for the Insane, Washington, D. C.; *Secretary-treasurer*, Professor Edward Franklin Buchner, Johns Hopkins University. To serve three years as members of the council: Professor James Franklin Messenger, State Normal School, Farmville, Va.; Professor Robert Morris Ogden, University of Tennessee. Other members of the council are: Dr. William Torrey Harris, Washington, D. C.; President D. B. Purinton, West Virginia University; Professor James Mark Baldwin, Johns Hopkins University; Principal Reuben Post Halleck, Louisville, Ky.

UNIVERSITY AND EDUCATIONAL NEWS

MRS. ESTHER GOWEN HOOD has given the University of Pennsylvania \$100,000 to estab-

lish graduate fellowships in the law department. The gift is a memorial to her father, the late Franklin B. Gowen.

MR. ADOLPHUS BUSCH, who last August promised to contribute \$50,000 towards the \$300,000 necessary for the erection of the new building for the Germanic Museum at Harvard University, has increased his gift to \$100,000.

THE General Education Board has offered to give Bryn Mawr College \$250,000 on condition that friends of the college subscribe \$280,000 by June, 1910. This is in addition to the \$100,000 recently given by the alumnae. Of this sum \$130,000 is to be used to pay the debt of the college, and the balance is to be reserved as an endowment fund.

THE building for the new California Museum of Vertebrate Zoology, at the University of California, is now under construction. Its cost, which is to be about \$14,000, is to be met in part by the regents' appropriation of \$7,000, and in part by an arrangement with Miss Annie Alexander, the patron of this new department, whereby she adds \$7,000 with the provision that her annual grant for maintenance for the next seven years shall be \$6,000 instead of \$7,000, as at first proposed by her.

THE regents of the University of Colorado have authorized the establishment of a summer laboratory for botany and zoology at Tolland, Colo., altitude 8,889 feet. The laboratory will be in charge of the regular instructing staff of the university, and there will be courses in elementary biology, plant anatomy, plant taxonomy and ecology. The location of the laboratory is such that students can study the plants and animals of all the different life zones from plains to alpine heights. Work done at the laboratory will count toward a degree in the university.

DR. FAIRBAIRN, who will retire from the principalship of Mansfield College, Oxford, at Easter, has given to the college his valuable theological and philosophical library.

DR. E. A. NOBLE was installed as president of the Woman's College of Baltimore on February 2, when addresses were delivered by

President Noble, Dr. H. S. Pritchett, president of the Carnegie Foundation for the Advancement of Teaching; Dr. Elmer E. Brown, U. S. commissioner of education; Dr. Ira Remsen, president of the Johns Hopkins University and Mr. John E. Semmes, president of the Baltimore school commissioners.

DR. FRANK L. McVEY has been elected president of the University of North Dakota. He was formerly professor of economics at the University of Minnesota and is now chairman to the tax commission of the state.

THE trustees of Columbia University have appointed Dr. William G. MacCallum, professor of pathological physiology in the Johns Hopkins University, to be professor of pathology in succession to Dr. T. Mitchell Prudden, who will retire from active service on July 1 next. At the same time the trustees have made provision for the development and extension of the departments of bacteriology under professor Philip H. Hiss, Jr., and of clinical pathology under Professor Francis C. Wood. Increased attention will be paid by these departments to the needs of advanced students and investigators.

At the College of the City of New York, Dayton J. Edwards has been appointed tutor in natural history. He is a graduate of the University of Maine, and has lately been an assistant at Columbia University.

Mr. G. H. Cox has been appointed instructor at the University of California in geology and mineralogy.

DISCUSSION AND CORRESPONDENCE

EDUCATION AND THE TRADES

TO THE EDITOR OF SCIENCE: In your issue for November 14 Mr. William Kent asks a question which interests me greatly and which, although I can not answer, I believe I can lay down the lines along which the answer must be made.

In the first place, I wish to express my unqualified approval of the letter of Stella V. Kellerman in your issue of November 18, with

which Mr. Kent expresses agreement, but which causes him to ask the question referred to. Latin, Greek and the mathematics have been taught for so many centuries that we have learned how to get out of them the highest possible degree of pedagogic value. This merely means that we have learned how, by means of studies of this character, to get hard work out of the student, while at the same time we maintain his interest. I assume that the pedagogic value of a study is largely comprehended in the possibility of teaching in the manner above mentioned. A great many people who honestly believe that our system of education should take more account of the daily affairs of life fear that when we replace any of the old studies by new ones which relate to modern industries, the work of the schools will lose its pedagogic value. Speaking in a general way, I believe this will be true, but this is not because the new studies do not have this value in them, but because we have not yet learned how to get it out of them. I believe there are some things which have higher pedagogic value than anything taught in our schools to-day, else why is it that with only 29 per cent. of our population actually living on the farm, with miserably poor school facilities as compared with our city population, this 29 per cent. furnishes about 70 per cent. of the leaders in every phase of activity in this country?

The point I wish to make is further illustrated by an instance that occurred in connection with the school garden work in Washington city schools. The teacher in charge had found difficulty in getting boys twelve to fifteen years old to lay off the plats properly. Two little boys, six and eight years old, from the hills of Virginia, came into school, never having seen plats laid off, but it was found that even the younger of these, if put in charge of a squad of boys twice his age, would have the work done according to directions. This greatly puzzled the teacher, and she asked me to explain it. I gave as an explanation the fact that these two small boys had enjoyed better pedagogical advantages than the others. But the teacher thought this im-

possible, as the smaller one had been to school only one year, and that in a little log cabin up in the hills. But when I called her attention to the fact that these boys had lived on a farm where they had been taught to assume responsibility and to do things, she agreed with my explanation.

I believe that it is the pedagogical value of farm work and the chance of placing responsibility on the child that has more than anything else to do with the development of efficiency and character in farm children, and this accounts for the fact that 29 per cent. of our population on the farms furnishes 70 per cent. of the efficient men in this country.

We have much yet to do before we understand the whole of this question. I believe, however, it is possible to outline a course which shall deal directly with the industries of our people and which will not only better fit pupils for their life's work, but will even fit them for college better than the best of our present high schools. We all recognize that because of our ignorance of the real principles involved in training the young mind, a lot of experimenting must be done before we have arrived at a final solution of this important question. The criticism I have to make of our school system is that we have neglected these essential experiments. It is high time that earnest effort be made in this direction.

W. J. SPILLMAN

U. S. DEPARTMENT OF AGRICULTURE

THE SIMPLE VS. THE COMPLEX IN SCIENTIFIC THEORIES

THERE seems to be a growing feeling that our present hypotheses concerning the structure of matter, and its relation to electricity, are becoming unsatisfactory. The reason for this is the increasing complexity of the phenomena, as we see them, and of the corresponding explanations which this involves. This feeling does not seem to be well founded. A former cave dweller, who has been for a few thousand years an inhabitant of some of the regions which Dante has described, would find our modern life an array of very complex phenomena.

He would observe that empty apartment houses attract homeless families. He would learn that this could not be accounted for by Newton's law of gravitation, although gravitational attraction between houses and people certainly does exist. He might feel inclined to give up Newton's law, because it does not explain all attractions. He finally learns that ether waves are involved in this phenomenon. The people must see the house before it can have any attraction for them. He would learn that the architecture of the house really appeals to the minds of these people. Being something of a philosopher, he constructs a mental field of force, which lays hold of the building and its surroundings, and which proceeds from the conscious beings. He is greatly interested in seeing that people appear very much alike, while houses differ very greatly in construction, in material and in mass.

As he has not yet learned anything about electrical and kindred phenomena, our visitor may be excused if he refers to the people as negative electrons or ions, and to empty houses as positive ions. When a house contains families enough, so that it ceases to have any attractions for more, he calls the combination an atom. He observes that more people can be forced into a house already normally filled, but the motive forces must come from some external source.

He finally learns that a family which has been more or less forcibly ionized, and is about to enter a new home, must deliver to its former occupant and owner, the value-equivalent of a certain number of foot-pounds of mechanical work previously done. The value-equivalent of this mechanical work may exist in the form of a certain number of grams of some valuable substance which is actually delivered. The value to be transferred may also exist potentially in the form of credit at a bank. The transfer of this value may then be effected by entries in the books of the bank, which transfer credits from one customer to another.

By the time our visitor has learned all these well-known things, it would appear that he

should not be greatly alarmed at present developments concerning electrical phenomena.

We know that molecules on the sun are in constant wireless communication with molecules on the earth. We can partially interrupt this communication by interposing a screen having a diameter of a centimeter or two. The molecules within the shadow now receive impulses transmitted to them by those outside of the shadow.

Here we have an action which is sufficiently amazing. Any explanation which we might make of it could not involve anything more wonderful than the action itself.

After we admit the existence of matter and of electrical phenomena, as we now know them, why may we not assent to the proposition that all atoms of matter are composed of positive and negative electricity or of positive and negative ions? This is essentially Franklin's hypothesis, deprived of its occult features, by reason of what has since been learned. The conductors in a power service are then aggregations of positive ions, or of positive electricity. The negative ions, or, as Franklin would have stated it, the electrical fluid, flows through what we now call the positive ions. Their rhythmical transfer from atom to atom accounts for the Joule effect. In addition we may have conditions which involve an actual and sudden transfer of kinetic energy from the moving negative ions to the positive ions. Such a case we have in the electric arc, which seems to me to be mainly a Thomson effect.

It is now established that the positive and negative discharges, which Wheatstone examined with the revolving mirror, are in the nature of compression and rarefaction waves. They are waves in Franklin's fluid. The negative terminal of any battery or dynamo is the compression terminal. From this terminal Franklin's fluid flows.

The writer has obtained photographs of the Wheatstone sparks and Wheatstone's conclusions concerning direction of propagation of the discharges from the terminals have been fully verified.

FRANCIS E. NIPPER

SCIENTIFIC BOOKS

Research in China. In three Volumes and Atlas. Vol. I., Part I. *Descriptive—Topography and Geology.* By BAILEY WILLIS, ELIOT BLACKWELDER and R. H. SARGENT. 4to, pp. xiv + 353 + index. Pls. LI.; figs. 65. 1907. Vol. II. *Systematic Geology.* By BAILEY WILLIS. 4to, pp. v + 133 + index. Pls. VIII. July, 1907. Published by the Carnegie Institution of Washington.

These admirably written and illustrated volumes should be read by all scientists interested in the geology of Asia and also by those interested in the larger problems of diastrophism and geologic history. The first and larger volume will be used more especially as a work of reference for details of Chinese geology; the second volume treats the same material in a condensed and systematic manner, following the course of geologic history and covering to some extent the whole of eastern Asia. Applying throughout the recently developed principles of diastrophism and physiography, a field of research in which the senior author has previously done distinguished work, these volumes mark a distinct advance over the previous comprehensive treatises dealing with this region, von Richthofen's "China" and Suess's "The Face of the Earth." The atlas, by the incorporation of Chinese characters, has been made readily available to the Chinese, and in the modern educative awakening of China such a publication dealing with that portion of the world may be of material aid in stimulating an interest in the earth sciences. It must not be thought, however, with national self complacency that the general educative effect need be restricted to China. The photographs and descriptions of certain districts bring home the desolation which may result from reckless deforestation, with the consequent sweeping of soils from the hill-sides and burial of valley alluvium beneath sand and gravel. This is a lesson the American people still need to learn and the material has already been utilized by the *Outlook* and the *National Geographic Magazine*.

The route of the expedition lay first into the Shantung peninsula, thence from Peking southwestward through north central China

to the Yang-tzi-kiang. In so far as the survey was necessarily rapid it partook of the nature of a reconnaissance and was restricted to type areas and to limited widths of territory, but it was of a character greatly superior to most reconnaissances in that the topography and geology within these limits were accurately mapped and comprehensively studied. Future work, therefore, needs simply to extend what has been already so well begun.

A brief summary is not included in the publication and a review may, in passing, mention the prominent features of the geologic history as set forth in the second volume. The Archean is restricted by the author to the metamorphic schists and gneisses of indeterminate character associated with a large proportion of metamorphosed igneous rocks, which by their intricate structure and inferior position to the oldest pre-Cambrian recognizable sediments are marked as belonging to a distinct and older system. The overlying Proterozoic was chiefly studied in the Wu-Tai-Shan and is divided into two systems, the eo- and neo-Proterozoic, the local Chinese names being omitted in this review. The eo-Proterozoic embraces three series separated by two unconformities.

Von Richthofen placed this system in the Huronian, using the latter term, as was commonly done thirty years ago, to suggest pre-Paleozoic rocks of green color. He did so with reserve, however, and the stricter usage of the term as it is now adopted does not permit us to maintain an exact correlation.

Willis points out, however, the strong similarities of these three series to the three Huronian series of the Lake Superior region and Van Hise has more recently compared them with still other formations of other regions similar in lithologic character and age relations. As Willis states:

The general relations to the Archean and neo-Proterozoic are similar in both continents, and the effects may well have been due to a general terrestrial cause which became active at about the same time, in regions remote from one another.

Between the eo- and neo-Proterozoic occurs a stratigraphic break of the first order, indicated both by a great unconformity and by

the folding and metamorphism of the lower system which are absent from the upper. The little altered, slightly slaty beds of the neo-Proterozoic resemble the Paleozoic above far more than the eo-Proterozoic below. At least 10,000 feet of slates, limestones and quartzites are embraced in this system. After a period of diastrophism the wide-spread land surface was reduced to a nearly perfect plain over which finally passed in places the Cambro-Ordovician sea. This pre-Paleozoic peneplanation was observed over a stretch of a thousand miles and is a feature of southeastern Asia.

The fact that Asia at the opening of the Paleozoic era was a featureless continent has important bearings. It limits the antiquity of mountain ranges, some of which have been discussed by eminent writers as of pre-Cambrian date, as elevations which have survived since that remote time; and it affords a basis of inference regarding a cycle of inactivity, which was common to other continents as well.

The marine invasion which initiated the Paleozoic sedimentation began in the late Lower Cambrian and gave rise to the Sinian group, extending to the Middle Ordovician. In central China the Sinian is composed of limestone, apparently to its very base, but in north China the characteristic strata of the Lower Sinian are red deposits. In south China, latitude 31° north, near the base of the Sinian and conformably interbedded between a quartzite below and marine limestone above occurs the bed of tillite which has attracted so much attention on account of the profound significance of this early glaciation near the level of the sea.

The Lower Ordovician strata are overlain by Upper Carboniferous, but without discordance of dip, implying prolonged quiet with most of the continental surface lying near sea level. The Carboniferous is characterized by marine deposits in the south, by continental deposits in the north. The transition to the Mesozoic is not marked by a sharp division plane, but by shrinkage of the seas and an increase in the proportion of continental deposits. At the same time Permo-Mesozoic diastrophism was pronounced and the present

structure lines of Asia were largely established. By the Cretaceous, however, Asia was again a low and featureless continent.

The Cenozoic history is one of erosion and land deposit. The Cretaceous peneplain conditions were continued at least in southern Asia through the Eocene and Oligocene and well into the Miocene, when occurred the epoch of mid-Tertiary compression resulting in folding. Since then there have been extreme effects of vertical warping unaccompanied by folding and chiefly of Pleistocene age. The evidence of the latter is largely physiographic and indicates "one of the most remarkable diastrophic movements of which we have knowledge." The Neocene and Pleistocene warping and faulting are believed to have produced differences of elevation exceeding 20,000 feet. Davis and Willis are thus in accord and stand in opposition to the earlier views of European geologists, in that these American investigators hold that the elevations due to Permo-Mesozoic folding or older epochs of diastrophism were long since planed away by erosion and are not the causes of the present relief. These views, developed first in America, are thus made of circumterrestrial application and may be regarded as the great contribution of physiography to geologic theory.

The paleogeographic maps are a feature of this report, as is also the map showing the results of the recent diastrophism.

In the final chapter Willis considers the bearing of the previous facts and conclusions upon the problem of the continental structure of Asia. No adequate outline of this chapter can here be presented. In brief, however, he finds that the continent may be resolved into positive and negative elements, the former areas tending to stand high, the latter tending to stand low. These tendencies are latent during comparatively long periods of quiet and resultant peneplanation, but become operative during epochs of diastrophism. The compressive movements, on the other hand, have pressed and welded the positive elements together, the axial directions of folding representing the compression of the negative zones lying between.

The cause of the diastrophism Willis ascribes to differences in specific gravity, restricted according to Hayford's determination to the outer hundred miles of the earth's body; the vertical movements being chiefly due to isostatic readjustment between the several continental elements, the compressive movements being due to the tendency of the heavier oceanic segments of the earth to spread and underthrust the outer portions of the whole continental mass.

For more than a third of a century the incompetency of secular cooling of the outer crust to account for diastrophism has been pointed out,¹ though it still finds credit in many text-books. Chamberlin, recognizing this, has constructed a hypothesis by which periodic compressive movements are ascribed to a shrinkage of the centrosphere and not the lithosphere. Willis goes still farther and obviates the necessity of postulating shrinkage of either the inner or outer earth. His hypothesis² thus belongs to that group to which O. Fisher and Dutton have previously contributed.

This must be regarded as a most suggestive working hypothesis, opening the field still wider to investigation, and may serve to destroy still more the false confidence regarding the cause of crustal movements which was felt by geologists of a previous generation, owing to the narrowly limited hypotheses then in vogue.

The hypothesis advanced by Willis is an extension of that proposed by Dutton, who ascribed folding to that subcrustal horizontal creep from the low toward the high elements which is necessary to isostatically restore the initial elevation of the high and the initial depression of the low.³

In the form in which Dutton stated the hypothesis it appears insufficient, since the

¹ C. E. Dutton, "A Criticism upon the Contractual Hypothesis," *Amer. Jour. Sci.*, Third Series, Vol. VIII., pp. 113-123, 1874.

² C. E. Dutton, "On Some of the Greater Problems of Physical Geology," *Bulletin of the Philosophical Society of Washington*, Vol. XI., pp. 51-64, 1880.

horizontal movement shown by folding seems far in excess of the subcrustal creep in the outer fifty or hundred miles of the earth's crust needed to restore the isostatic adjustment between the regions on the two sides of the zone of folding. Furthermore, the vertical readjustments which take place in epeirogenic movements are not simultaneous in origin with the horizontal movements.

Somewhat similar difficulties seem to face the larger hypothesis of Willis in which continental and oceanic segments are concerned rather than adjacent geanticlines and geosynclines. The average continental surface stands about three miles above the average ocean bottom, owing to the lighter subcontinental matter. The isostatic compensation, as Hayford has shown, is complete at a distance of about seventy to a hundred miles from the surfaces. A column of matter on the edge of an oceanic segment and extending to this depth will consequently have its top pressed seaward by a pressure due to the greater height of the continental mass, a pressure resisted by the rigidity of the surface of the oceanic segment. The foot of the column, however, will not be strained in either direction, since the weights of the continental and oceanic segments at this depth are equal. Any intermediate point in the column will be pressed seaward with an intermediate pressure.

The initial cause of that horizontal movement which is due to isostatic adjustment on the continental margins would, therefore, be an outward spreading of the continental margin by flowage and normal faulting. The surface being lowered by this means, the subcontinental pressures would be lessened and a landward movement of the lower zone of the oceanic segment would in turn tend to take place, restoring in this manner a part of the initial height. It is difficult to see, however, how compression of the continental surface could ever occur as a result from this spreading except for local and minor adjustments, since the flowing outward of the surface is the operating cause. In so far as sediment from the continents is deposited on the bottom of the oceanic segments, however, and the surfaces of the two are brought toward a common

level, the tendency of the top of the continental segments to spread outward will be checked and a tendency for the lower part of the oceanic segment to underthrust the land will arise. But the greater part of terrigenous sediments have been deposited within continental geosynclines, or upon the lower continental elements, or as submarine deltas building slightly outward the continental shelves. The isostatic readjustment should, therefore, be largely between the high and low continental elements and it is not clear that sedimentation could account in any large measure for such a crowding together of the continental elements by pressure from the oceanic segments as the structure of Asia seems to suggest. Furthermore, Willis has shown that the present great relief of Asia is the result of a very recent movement unconnected with the Permo-Mesozoic folding and but partly originating in the mid-Tertiary period of orogenic activity. It seems best, therefore, to consider that vertical movements, bringing about isostatic adjustment, are but indirectly connected with the great compressive movements, following after them to a greater extent than accompanying them; due to a seeking for an equilibrium destroyed on the one hand by erosion and sedimentation, on the other by changes of specific gravity from within, induced partly by the previous horizontal compression. Horizontal compressive movements, on the other hand, characterized by their large amount and brief duration and separated by relatively long periods of quiet, seem to have found as yet no better explanation than that advanced by Chamberlin, as due to a progressive shrinkage of the entire central portion of the earth, resisted by the rigidity of an outer unshrinking zone many hundred miles in thickness. This gives the necessary mechanism for the gradual storage of compressive stress and its periodic discharge by yielding of the outer zone, a yielding characterized by the mashing of geosynclines and other lines of weakness in the outer shell, and the underthrusting of the continental surfaces by the lower and structurally stronger oceanic segments.

JOSEPH BARRELL

YALE UNIVERSITY

Principles of Breeding. A treatise on thremmatology, or the principles and practises involved in the economic improvement of domesticated animals and plants. By E. DAVENPORT, M.Agr., LL.D., with appendix by H. L. RIETZ, Ph.D. Boston, Ginn & Co. 1907. Pp. xiii + 727.

It is likely that most writers will follow Bateson in using the broader term "genetics" for the subjects covered in this volume, rather than the older and more restricted term "thremmatology," proposed by Lankester, even if for no other reason than ease of pronunciation. However this may be, contemporary investigators seeking the facts of development, variation and heredity are fast accumulating vast quantities of data, past investigations are receiving renewed attention in the light of recent discoveries, and the author who undertakes the often thankless task of compiling a text-book from the varied lines upon which these subjects border, deserves the gratitude of all who are interested in the field. Dr. Davenport brings to his aid fifteen years' experience in presenting these matters in the class-room, and the result is a well-planned and logically developed treatise, written in such clear English that a college student should have little difficulty in seeing the matter with the author's eyes. It may be that all students of genetics will not accept his views upon disputed subjects, for they are the views of an ardent biometrician; it is positive that there will be a difference of opinion as to the relative importance of certain phases of the subject; yet this is the fate of all text-books, particularly those in a new field. There is hardly a doubt but that the statistical method of dealing with problems of heredity is unduly favored; and when the author asserts that "it is the only reliable method of attacking problems in transmission," cytologists and investigators using pedigree culture methods will lend their approbation only so far as to admit that a knowledge of the theory of statistics is a valuable *adjunct* to any line of work. On the other hand, the method of handling the

older debated questions of general biology—acquired characters, etc.—is eminently fair and equitable.

The book is divided into four parts: in the first three, of increasing length, are discussed the kinds of variation, the causes of variation, and the transmission of characters, while the much shorter fourth part is devoted to practical problems. In a short appendix Dr. Rietz gives an excellent introduction to the theory of probabilities. Additional literature is cited at the end of each chapter, which, in the hands of a teacher familiar with all branches of the subject, would be a valuable basis from which to make selected lists for collateral reading. Unfortunately the classics cited are not distinguished from absolutely valueless articles, and such extended lists might thereby become rather more of a hindrance than a help. The originals are cited only when in English; the foreign work, which forms a large portion of the literature in genetics, is therefore noticed only in the form of English abstracts.

After an introductory chapter on the general nature of variability, variation is treated under the heads morphological, substantive, meristic, functional and mutational. The discussion under the first two heads, variations in size and quality, are quite short. We miss any consideration of the facts relating to the difference between mere bigness due to nutrition and inherited size due to gametic structure, which from its importance to the breeder we might reasonably expect. More extended treatment is given to the third type, the examples and text figures being drawn almost wholly from Bateson. Under functional or physiological variation, however, we are indebted to the author for a wealth of new illustrations, many of which are from experiments with beef and dairy cattle and with maize, that have never before been published. Under mutations the author gives to the reader the same impression (and the reviewer believes this time unintentionally) that has caused, and is still causing, false impressions among out and out Darwinians as to the true con-

ception of a mutation. All opponents and many adherents of de Vries seem to be able to conceive a mutation only as the addition or loss of a complete character and therefore a wide jump. That such a change sometimes takes place, the mutationist believes, and so also does the Darwinian (or at least so also did Darwin), but by far the larger number of mutations are quantitative changes in characters already possessed, i. e., simply the production of new modes as centers for linear fluctuation. The difference between fluctuations and mutations is merely in their transmission.

Part II.—Causes of Variations—begins with an admirable non-technical description of cell division, followed by a development of the actual theme, in which are taken up first, internal causes which affect the individual, and second, those which affect the race. One can not help but be struck with the logical manner in which the author disposes of old, popular myths, such as telegony and intra-uterine influences, by appealing to the law of error. It is also gratifying to know that he has found by correspondence that practical breeders, for example dog fanciers, seem to be outgrowing their past childlike faith in these things. It is likely that this book will do much toward changing such superstitions as belief in maternal impressions in the next generation of animal breeders. Modern biometry as based on the theory of probability seems to the reviewer to have its greatest value to practical breeders in showing how illogical it is to consider isolated cases as proofs of a biological principle, and considerable emphasis is given by the author to this point. It is hardly likely that many present-day farmers will study thoroughly so bulky and technical a volume, although the author hopes to reach them, but their sons who have had some training in genetics in our agricultural colleges will be given a broader and more scientific point of view.

A large portion of the remainder of Part II. is devoted to external causes of variation. This portion is almost wholly an abstract of C. B. Davenport's "Experimental Morphol-

ogy." Then, as a transitory introduction to Part III. on "Transmission," follows a very judicial treatment of the inheritance of acquired characters. Here, again, the theory of probability is utilized to show that instances of apparent transmission of somatic modifications are, at least, doubtful—a judgment which the most ardent Lamarckian could hardly question.

A considerable percentage of the remainder of the part is devoted to pure biometry which the author believes to be the coming method for attacking genetic problems. The elements of biometry are explained with greater clearness than in any other English publication, and as such are to be highly recommended. The elaboration of the results of Karl Pearson and his school, however, shows too great a trust in Pearson's lame biology.

It will be exceedingly unfortunate if there is a promulgation of this idea of certain biometricians, namely, that valuable biological conclusions can be drawn where there have been no biological premises, by the mere fact of complex, mathematical treatment. As an example of a biometrical explanation which explains nothing the following may be cited (p. 537):

The principal function of selection, therefore, is to *alter the type, not to reduce variability*, and the facts here cited show the inherent impossibility of "fixing" the type in the sense that individuals will not depart from it. But, on the other hand, the same principle assures us that, however much we improve by shifting the type, there always remains sufficient variability for further selection, *and so long as variability remains there is hope and possibility for still further improvement.*¹

Compare this view with that of Johannsen. (By the way, the epoch-making work of Johannsen on "pure lines" is not mentioned.) The latter considers the variation's curve of a quantitative character of any general population to be made up of numerous family lines. Members of these family lines are true to their own type, their fluctuations being due to nutrition, etc., and not inherited. The rôle of selection, therefore, is to isolate a family

¹ Last clause italicized by E. M. E.

line from a heterogeneous mixture of small types differing gametically among themselves. Here we have a real explanation compatible with the belief that to be inherited variations must have affected the germ cell structurally—a view to which the author apparently adheres.

Mendel's original investigations are briefly discussed by the author, but all of the numerous, recent contributions along this line are left untouched. Of course the immense amount of labor necessary to compile a book of seven hundred pages in a new subject would necessitate the work being actually behind the date of the preface, but one would like to see more notice taken of the many valuable investigations of contemporary biologists. A more extended consideration of late cytological and Mendelian research would have changed materially the author's treatment of atavism, prepotency and the determination of sex.

The work as a whole, however, brings together an enormous number of facts along diverse lines, and, though largely zoological, will undoubtedly prove of great value as a reference basis for a course of lectures on the subject, even if the new facts, which are continually being contributed in such profusion, make it of less value as an ironclad text-book.

EXPERIMENT STATION

Mushrooms, Edible and Otherwise. By M. E. HARD, M.A. Large octavo. Pp. xii + 609, with 504 half-tone figures from photographs, many of them full-page plates. Distributed by The Ohio Library Co., Columbus, Ohio.

Under the above title Mr. Hard has given us an exceedingly interesting and valuable book upon a subject in which every one is interested, whether he is a botanist or not. The book is intended primarily for the beginner and a chapter including such subjects as, Why Study Mushrooms? Mushrooms and Toadstools, How to Preserve Mushrooms, etc., and An Analytical Key, is written in words so simple and yet so accurate that even the beginning student will gain a ready hold

upon the group and will not be encumbered with a load of useless and unscientific data. As the late Dr. Kellerman states in the introduction, "The author does not write for the specially educated few, but for the mass of intelligent people—those who read and study, but who observe more." Thus the work is intended to appeal more especially to the people at large, but there is also much good in it for the college student of mycology. The generic and specific descriptions, and the great range of forms depicted in word and picture, are so nicely worked out that the book is one of the very best of the American publications of its kind. Without doubt this is the finest and most carefully arranged set of half-tone figures of American Agarics to be found in a single book.

A little more than one half (349 pages) of the book is devoted to the Agarics, the remainder being divided between the Polyporaceæ, Hydnaceæ, Phlephoraceæ, Clavariaceæ, Tremellini, Gasteromycetes, Ascomycetes, and a chapter each on the Myxomycetes, Recipes for Cooking Mushrooms, and How to Grow Mushrooms. These chapters are characterized by the same interesting style and excellent illustrations.

The author is determined that every one shall come to know mushrooms, first from the practical side to be able to identify the edible ones, and finally to know them from a more scientific standpoint, and then to be led to the broader study of mycology as a whole. The student of this book will unconsciously be led along this very path. As one turns the pages of the book he is delighted almost beyond expression, and he feels that Mr. Hard has rendered a great service to science in general and to mycology in particular in giving us this excellent work.

RAYMOND J. POOL

THE UNIVERSITY OF NEBRASKA

SPECIAL ARTICLES

NOTES ON THE FIRST GENERATION HYBRID OF
OENOTHERA LATA ♀ × *O. GIGAS* ♂

DURING the summer of 1907 three offspring of *Oenothera lata* ♀ × *O. gigas* ♂ were reared to maturity in the garden at the Station for

Experimental Evolution and observations upon the somatic chromosomes of these plants were embodied in a report read at the Seventh International Zoological Congress.

The peculiar combination of parental vegetative characters in each of these hybrids, associated with a certain fixed number of somatic chromosomes, suggested the desirability of repeating the cross upon a much larger scale in hopes of throwing some light upon the behavior of chromosomes in inheritance and of determining, if possible, whether number, size and shape of chromosomes are regularly associated with the inheritance of certain definite external characters.

In a previous note *O. gigas* was reported to have double the number of chromosomes found in *O. lamarckiana*, with evidence to suggest that the number may vary within a limited range among individuals of the species.¹ Gates² later sustained the count of 28 for *gigas* from observations of the germ-cells. In an earlier paper he reported 14 chromosomes for *lata*.³ The few individuals of this species which I have examined have given 14 and 15 chromosomes with considerable, though not conclusive, evidence that a single plant had 16.⁴ The number for each individual however remained constant.

The striking differences in the number of chromosomes of *lata* and *gigas*, associated with marked differences in external characters, caused the progeny of a cross between individuals of these two species to become a subject of particular interest. Seeds for the first generation offspring of *O. lata* ♀ × *O. gigas* ♂ were secured from guarded pollina-

tions through the kindness of Dr. G. H. Shull. The hybrids arising therefrom were the progeny of a single pair of parents; the pistil parent in this case being a mutant which arose from a culture of pure-bred *lamarckiana* and the pollen parent a pure-bred *gigas*. Seventy-seven young rosettes were transferred to the experimental garden early in May, fixations having previously been made of the root tips of 50 of this number for the study of somatic chromosomes.

By sowing seeds in the greenhouse early in February and transplanting rosettes to the garden as soon as danger of frost is past, *lata*, like *lamarckiana* and others, may readily be brought to flower the first season. *Gigas*, on the contrary, is strongly biennial and even when subjected to the same conditions as *lata* from seed-sowing to maturity only a small percentage can be expected to flower and ripen seeds the first season. Consequently, the fact that 44 of these hybrids were annuals is of considerable apparent significance. It is, however, unsafe to conclude that this is a manifestation of an hereditary character, inasmuch as the majority of those remaining in the rosette stage were subjected to slightly different environmental conditions, having been transplanted to the garden 9 days later than the majority of those which proved to be annuals, and transferred to somewhat richer soil. Designating the two plots as east and west gardens, 47 young rosettes were transplanted to the former May 1 and 3 on May 10. Of the first lot, 37 came to flower during the season, 3 died and 7 have gone into the winter as rosettes.

Twenty-seven rosettes were transferred to the west garden May 10, of which 5 came to flower during the season, though very much later than the majority of those of the same class in the east garden.

The somatic chromosomes of 40 of these hybrids (25 of which were annuals) have been carefully studied and the remaining 10 will be included in the final publication to appear shortly. To insure accuracy of chromosome counts, none was considered conclusive unless sustained by 10 or more perfectly clear figures distributed through 2 or

more (usually 3 to 6) separate fixations from each plant. In every case but one, referred to later, the number remained constant for each individual throughout the several fixations. Corroborative evidence was also secured in a number of the exceptional forms by a study of tapetal cells. Hundreds of figures were carefully examined to determine whether individuality in size and shape of chromosomes could be recognized, but no evidence whatever was secured to demonstrate that any such differences exist.

In the majority of these hybrids the exact number of somatic chromosomes has been determined with certainty; but owing to the fact that a few of the intermediates and several of the *gigas*-like hybrids yet require the study of more sections to settle the question of one or two chromosomes more or less, it will be necessary for the present to group them merely under the heads of *lata*, *gigas* and intermediate. The identifications are based both on chromosomal and vegetative characters. While these groupings are sufficient in the main for all classes, II. and III. can well be further subdivided with respect to external characters.

CLASS I., *lata*, is represented by 2 individuals appearing as true *lata* in every point, indistinguishable from *lata* mutant from earliest seedling stage, and having *lata* number of chromosomes—15. Both annuals.

CLASS II., *gigas*, consists of 6 plants having *gigas* number of chromosomes (30 in each case so far definitely counted). Two of the 6 plants were annuals; one resembled *gigas* far more strongly than any other hybrid coming to flower in the garden, yet hardly to be classed as a good typical *gigas*. The second annual resembled the individuals of Class III. in a few, and pure *gigas* in the majority, of its vegetative characters. A peculiar exceptional circumstance is connected with the microscopic study of this plant. Fixations of root-tips, prepared April 3, gave an intermediate number of chromosomes. Another dated April 11 showed the *gigas* number with equal clearness, while a third was poorly fixed and gave no hint to settle the question. A fourth fixation of tapetal cells was made in August

and clearly demonstrated the higher number. It therefore seems probable that the first fixation was taken from a member of Class III., and the confusion arose from an error in labeling. It is upon the basis of this conclusion that I have included this plant within Class II. rather than III.

The third plant under this head (biennial) was characterized in early seedling and rosette stages by whitish markings, so conspicuous in *albida* at corresponding stages of development. It differed markedly from the latter, however, in shape of leaf. The three remaining biennials differ considerably from one another, but equally pronounced differences have been noted among individuals of pure *gigas*. The members of this class, however, form the least homogeneous group of the three with respect to external characters.

CLASS III. is represented by 32 individuals, 21 of which were annuals. A portion of these had 22, others 23 and some possibly 21 chromosomes, although evidence is not yet complete in regard to the last. With respect to vegetative characters, the plants of this group fall readily into 3 subdivisions:

1. Consists of a single individual, remarkable for its narrow leaved, *gigas* type of foliage, utterly unlike that of *lata*. A single lateral flowering branch produced a few buds and flowers which were noted as "intermediate."

2. Is composed of those individuals which may be classed as true intermediates and includes 12 of the 21 annuals of Class III. The main features characteristic of this group are as follows: resembled *lata* in imperfect unfolding of petals, scarcity of pollen produced, sterility of pollen and shape of first buds; resembled *gigas* in size of corolla (with several exceptions), and various parts of flower, in red tinting of sepals (particularly in latter part of the season), and in general vigor of the plant.

3. Is in many respects the most interesting of all. It is composed of those individuals of class III. that have long slender buds, flowers with smooth petals and yield a moderate abundance of pollen. It may again be properly subdivided into *a* and *b*; the former consisting of three plants attaining the height of

lamarckiana and being indistinguishable from it in manner of branching and large number of flowers produced. A fourth member of this group bloomed late in the season and did not attain its full stature. The buds of these peculiar hybrids might have been classed as stout *lamarckiana* or slender *gigas*. The sepals remained conspicuously yellow, attaining near the end of the season a faint tint of red, like extracted *lata*s of this cross. The foliage resembled *gigas*.

The second half of this group consisted of four plants somewhat resembling the first in size and branching habits but, in three of the four individuals, distinguished from it by the deep red color of the sepals—strikingly resembling *rubrinervis* in this regard. The fourth plant had less deeply colored sepals and possibly should be placed in a subdivision of its own.

The appearance among the offspring of *O. lata* × *O. gigas* of plants with pronounced *lamarckiana* characters is puzzling. The combination of these with equally pronounced *gigas* characters, further associated with the intermediate number of chromosomes, precludes the possibility of the pistil parent having been accidentally fertilized by *lamarckiana* pollen. MacDougal¹ succeeded in fertilizing *lata* with its own pollen for the first time on record, and obtained seed which "gave rise to a progeny which showed only the constituents usually found in a progeny of this plant when fertilized by *lamarckiana*."

Study of the pollen of these hybrids is as yet in the initial stages, but some interesting observations have already been made.

Pollen grains of *O. lamarckiana*, *O. lata*, *O. nanella*, *O. rubrinervis* and *O. cruciata* are, so far as I have observed from the cultures growing at the station this summer, characteristically 3-lobed as figured by Gray² for *Oenothera*. Limiting observations to the first

two forms mentioned, ordinarily about 1 in 1,000 grains has been found to have 4 or more lobes, although as high as 15 per cent. has been observed in normal, typical individuals. Seven representatives of pure *gigas* were examined and the 3-lobed grain was found to occur as rarely in this species as the 4 and 4+ grains in *lamarckiana*. Four-lobed grains prevailed for most individuals of *gigas*, although these were commonly found mixed with 5-, 6-, 7- and even 8-lobed grains, usually decreasing in frequency with the increase in the number of lobes. A further interesting point brought out was the fact that certain individuals showed these extra lobes in all stages.

The study of the pollen of the hybrid progeny of *O. lata* × *O. gigas* was therefore of absorbing interest.

CLASS I. (two extracted *lata*s) showed 3-lobed pollen with an exceptional extra-lobed grain, as is characteristic for a *lata* mutant.

CLASS II., composed of two adults with *gigas* number of chromosomes gave each 4 and 4+ grains with an exceptional 3-lobed individual as is characteristic for pure *gigas*.

CLASS III. (hybrid number of chromosomes), pollen of seven individuals studied each gave a mixture of 3- and extra-lobed grains. The proportions have not yet been ascertained, but it is clear that the former are usually considerably in excess of the latter.

The sterility of *lata* is due not only to the scarcity of pollen produced, but to the large percentage of bad grains. The amount yielded by any form was found to vary with the individual, with the flower of the individual, and with the anther of the flower. Even the most fertile forms produce a surprisingly large percentage of bad pollen, and some of the above hybrids, notably certain members of Class III., subdivision 3, have been found to have as high as 90 per cent., although pollen was produced in moderate abundance. Inasmuch as *lata* yields but very little pollen, mostly bad, and *gigas*, while producing a considerably larger quantity, has in most instances a low percentage of good grains, it is not at all surprising that it was utterly impossible to artificially self-pollinate the majority of these

¹"Mutations, Variations and Relationship of the *Oenothera*," by D. T. MacDougal, A. M. Vail and G. H. Shull. The Carnegie Institution of Washington, Papers of Station for Experimental Evolution No. 9.

²Gray's "Lessons and Manual of Botany," revised edition, 103, fig. 316.

hybrids, although attempts were persistently repeated throughout the summer. However, a few seeds were obtained from individuals having respectively *lata*, *gigas*, and intermediate number of chromosomes and the plants derived from these will form the chief subject of study for the coming year.

To summarize briefly:

The first generation offspring of *O. lata* ♀ × *O. gigas* ♂ fall into three main groups with respect to external characters and number of chromosomes; namely, *lata*, *gigas*-like and intermediate. Considering external characters only, the latter two should be further divided and subdivided.

Numbers of chromosomes are closely associated with external characters in the first and last, and probably also in the second group.

Pollen grains of two parental forms differ in number of lobes and these are inherited.

STATION FOR EXPERIMENTAL EVOLUTION,

COLD SPRING HARBOR, L. I.,

December 7, 1908

MUCOR CULTURES

IN the study of the Mucoraceae for several years, some interesting facts concerning the development or rather the non-development of zygosporangia were observed. The experiments were made with the common *Mucor stolonifer* Ehrenberg. The media used were bread, pumpkin, orange, cornmeal, decoction of horse manure with gelatine, Pasteur's solution with gelatine, Hamaker culture medium.¹ The cultures were made with sterilized and unsterilized media. The spores for inoculation were taken from plants grown in the laboratory, from specimens collected for the herbarium, and from specimens sent to us by friends. In one thousand cultures not one zygosporangium was discovered.

In addition to the cultures, five hundred specimens of this species found growing spontaneously in different places were also examined but not one zygosporangium was observed.

Besides these experiments, many cultures were made and many specimens examined, a record of the exact number of which, however,

¹Hamaker, SCIENCE, XXIII, 710, 1906.

was not kept. It is a conservative estimate to say that five hundred observations of this kind were made. This makes a grand total of two thousand observations without a single zygosporangium.

Experiments were also made to determine the development of this *Mucor* under anaerobic conditions. The media used for these experiments were orange, bread and Hamaker culture medium. All were sterilized. In giving the results of these experiments below, the word cornmeal will be used for the Hamaker medium. Cornmeal is the principal constituent of the medium. The material for inoculation was kindly furnished by Dr. Niewland, of Notre Dame University.

Small wide-mouthed bottles were used for the cultures. The medium was placed in the bottles and the bottles then closed with cotton and all sterilized. After inoculation, the bottles were placed into Novi jars and the jars filled with gas. The jars with the bottles were then set aside for observation. The following results were obtained.

In Hydrogen.—On orange, mycelium developed but few sporangia, no zygosporangia; on bread, no development; on cornmeal, no development.

In Nitrogen.—On orange, mycelium and few sporangia, no zygosporangia; on bread, about the same result; on cornmeal, about the same result.

In Carbon Dioxide.—On orange, mycelium well developed but few sporangia; on bread, mycelium profusely developed, many sporangia, no zygosporangia; on cornmeal, no development.

It seems that the absence of oxygen is not a necessary condition for the growth of zygosporangia.

DAVID R. SUMSTINE

UNIVERSITY OF PITTSBURGH

THE BOTANICAL SOCIETY OF AMERICA

A UNION OF THE BOTANICAL SOCIETY OF AMERICA,

THE SOCIETY FOR PLANT MORPHOLOGY AND

PHYSIOLOGY AND THE AMERICAN

MYCOLOGICAL SOCIETY

THE third annual meeting of the federated societies (the fifteenth of the Botanical Society

of America) was held in the Eastern High School, Baltimore, Maryland, December 28, 1908, to January 1, 1909, under the presidency of Professor W. F. Ganong. Over sixty members were in attendance at the meeting, which seemed generally regarded as unusually successful. The arrangements made by the local committee for the American Association concerning rooms, stereopticons, etc., proved entirely adequate and satisfactory.

The officers of the society for 1909 are:

President—Professor Roland Thaxter, Harvard University.

Vice-president—Mr. A. F. Woods, Bureau of Plant Industry.

Treasurer—Dr. Arthur Hollick, New York Botanical Garden.

Secretary—Professor D. S. Johnson, Johns Hopkins University.

Councillors—Professor J. M. Coulter, University of Chicago; Professor Wm. Trelease, Missouri Botanical Garden; Professor F. E. Clements, University of Minnesota.

Five associate members were elected to full membership, and eight botanists were elected to associate membership.

The next annual meeting of the society will be held in conjunction with the American Association for the Advancement of Science.

Important features of the program were the special addresses given on invitation of the council by Professor Roland Baxter, of Harvard University, and Professor J. C. Bose, of Presidency College, Calcutta; the addresses on "Vascular Anatomy," by J. M. Coulter and E. C. Jeffrey; the symposium on "Present Problems in Ecology," with papers by H. C. Cowles, B. E. Livingston, C. H. Shaw, V. M. Spalding and E. N. Transeau; and, finally, the estimates of Darwin's work in botany, given at the Darwin Memorial Session of the society by Wm. Trelease, H. M. Richards and F. E. Clements.

It is planned to publish in full in *The American Naturalist* the addresses on "Vascular Anatomy," on "Plant Ecology," and those given at the Darwin Memorial Session. Reprints of these papers will then be distributed to members of the society.

The scientific session of the society on Thursday morning, December 31, was devoted to the reading of papers which were organized into two programs given simultaneously. Abstracts of these papers follow:

The Structure and Organisation of Pedicellum:

Professor R. A. HARPER, University of Wisconsin. By title.

Illustrations of Some of the Types of Coralline Algae: Dr. M. A. HOWE, New York Botanical Garden.

The speaker exhibited a series of lantern-photographs, illustrating the form, structure and habits of growth of the dominant types among the Corallinaceae. The specimens selected for photographing were collected chiefly on the shores of Newfoundland, Maine, Florida, Bermuda, the Bahamas, Jamaica and Porto Rico. Certain calcareous Chlorophyceae, often confused with the Corallinaceae by the earlier naturalists, were also illustrated. The structure of several genera of unsegmented corallines was exhibited by means of photomicrographs. Of special biological interest were photographs showing corallines growing attached to living corals and indicating competitive struggles for existence between calcareous plants and calcareous animals. The speaker alluded to the wide geographic range of the corallines and to the discovery by the late Professor Kjellman of extensive beds of *Lithothamnion glaciale* off the coasts of Spitzbergen and Nova Zembla, more than twelve degrees north of the Arctic circle. Mention was made, also, of recent investigations tending to show that reef-building and land-formation in certain regions have been due to the growth of calcareous plants fully as much as to the corals.

The Male Gametophyte of Dioon edule: Professor C. J. CHAMBERLAIN, University of Chicago.

The staminate cones of *Dioon edule* shed their pollen in September, the male gametophyte at this time consisting of a prothallial cell, a generative cell and a tube cell. The generative cell divides in October, forming a stalk cell and a body cell, and the latter divides in the following spring, giving rise to two sperms. The sperms are formed within two sperm mother cells and swim freely within the mother cells before they escape into the tube cell.

The blepharoplasts are first distinguishable in the body cell and are very probably of nuclear origin. The radiations about the blepharoplasts arise by a transformation of the cytoplasm, but owe much of their subsequent growth to granules of nuclear origin. During the transformation of the blepharoplast into the spiral band, the band is closely connected with the nucleus, both morphologically and physiologically.

The mature sperms not only swim actively by means of cilia, but have an amoeboid movement. In escaping from the pollen tube, they may be constricted to less than one fourth their normal

diameter, but readily regain their form. The cilia continue to move even after the sperm has penetrated the egg, but the nucleus soon slips out from the cytoplasmic sheath and moves toward the egg nucleus.

Some details in the transformation of the blepharoplast into the spiral band, as well as details in the origin and development of cilia, are better shown in *Ceratozamia* and will be treated in greater detail in the forthcoming paper on that genus.

Further Studies of Enotheran Cytology: Dr. R. R. GATES, University of Chicago.

In a recent paper¹ I described the method of chromosome reduction in *Enothera*, using *O. rubrinervis* and several of the other mutants as types. I have since examined the various stages of reduction in the wild *O. biennis* and in *O. laevifolia*, and the observations confirm in practically every detail the results recorded in that paper. In both of these forms the chromosome number is fourteen, the reduced number being seven.

The essential points in the method of reduction may be briefly stated as follows:

After synapsis a single thick spirem is finally formed, which breaks into a chain of fourteen chromosomes lying mostly attached end to end. These do not always pair with each other, but frequently lie unpaired on the spindle. In the heterotypic mitosis half of them pass to each pole. Each divides during the later stages of this mitosis, and the halves are separated by the homotypic mitosis. The first mitosis thus separates whole chromosomes and the second mitosis the (probably) longitudinal halves of these. The chromosomes become so nearly globular that the direction of this split is not easily determined.

On account of the weakness of the attraction between homologous chromosomes at the time of pairing, many of them lie unpaired on the heterotypic spindle; and this allows of occasional irregularities in their distribution. Such irregularities provide a possible basis for the origin of mutants having the same number of chromosomes but lacking certain groups of characters, provided, of course, that the chromosomes are qualitatively different.

The Type of the Genus Cactus: Dr. J. N. ROSE, U. S. National Museum.

Edaphic Conditions in Local Peat Bogs: Dr. G. P. BURNS, University of Michigan.

¹ "A Study of Reduction in *Enothera rubrinervis*," *Bot. Gaz.*, 46, 1-34, 1908.

Beginning with the open water, the plant societies usually found in the peat bogs near Ann Arbor are the aquatic, bog-sedge, bog-shrub, tamarack, maple-poplar and willow or marginal societies. A study was made of the distribution of these societies at different lakes and records were made of the variations in the edaphic factors influencing the different societies.

The data obtained indicate quite clearly that the position of the peat deposit is dependent upon the depth of the water and shape of the shore of the original lake and not upon the direction of the prevailing winds, as has been supposed.

Of the edaphic factors, the position of the water-table in the various areas is the most important. This is subject to wide variations. In the summer of 1905, April 24 to August 5, the variation under the different societies was as follows: bog-sedge, 0 cm.; bog-shrub, 17 cm.; tamarack, 31 cm.; willow or marginal society, 95 cm. In these outer areas fungi and bacteria can work to greater depths, changing the nature of the soil and rendering it capable of holding more and more available water, or in other words less xerophytic.

Continuous temperature records also show that the marginal areas are less xerophytic than those nearer the open water.

Stomata and Transpiration in Tradescantia zebrina: Dr. B. E. LIVINGSTON, Desert Botanical Laboratory.

The purpose of this study is to determine as well as possible to what extent the stomata are influential in causing the transpiration rate to be relatively greater by day than by night. By measuring the stomatal pores and calculating the relative diffusion capacities for night and day, it is found that this capacity in the daytime is about 2.6 times as great as in the night. The influence of the evaporating power of the air in this connection varies, of course, with weather conditions. The greatest difference observed shows an evaporating power for the day of 6 times that of the night. The smallest difference shows a ratio of 1.92. An attempt is made to calculate the transpiration ratio (day to night) by multiplying the evaporation ratio by the ratio of diffusion capacity. The result of this apparently shows that with direct sunlight the calculated transpiration rate for the day is too low, while with diffuse light it is too high. An average of nine tests with diffuse light shows the actual transpiration ratio to be 0.76 of the calculated, but individual tests showed a close approximation.

The conclusion is that, with diffuse light, the

variation in the size of the stomatal pores in *Tradescantia zebrina* (with the resulting variation in diffusion capacity) is amply great enough to explain that portion of the daily rise in transpiration rate which is not dependent upon the variation in the evaporating power of the air. With direct sunlight it appears that the stomatal variation is not large enough to explain this.

The Vegetation of Northern Zacatecas, Mexico:

Professor F. E. LLOYD, Alabama Polytechnic Institute.

A general comparison between the vegetation of the region indicated in the caption with that of other desert regions, more especially with that of the vicinity of Tucson, Ariz., in which the greater general density of the vegetation of the Zacatecas desert is pointed out, and an attempt is made to explain the difference upon the grounds of diversity in meteorological conditions as bearing on soil-moisture and evaporation.

The extended account embraces a year's observations of the meteorology, the topography and soils of an area of 2,000,000 acres, a somewhat detailed account of the plants and their distribution as related to the topography, together with observations upon the seasonal changes, and the adaptational characters in the vegetation which appear to be correlated with them.

The Presence and Absence Hypothesis: Dr. G. H. SHULL, Station for Experimental Evolution.

In explaining the behavior of what are now called Mendelian hybrids, Mendel assumed that pairs of antagonistic characters are represented by pairs of internal units, one member of each such pair of units coming from the one parent, the other from the other parent, and both existing side by side in the heterozygotes. De Vries laid great stress upon this conception in distinguishing between "varieties" and "species." This idea is perhaps yet the most commonly held, though it has recently become common to describe a Mendelian "pair" of characters in the terms of the presence and absence of a single character. There is no evidence of the existence of a pair of internal units or "allelomorphs" and the phenomena of incomplete dominance, reversal of dominance, etc., can be simply explained by the assumption that there is no paired condition of internal units. The dominance of the absence of a character over its presence is readily explained by analogy with many common chemical reactions, and while it may be assumed, as has been done by Bateson and Davenport, that what appears to be absence of a character may really be the presence of an inhibiting factor, this is not a necessary

assumption. It can be shown that absence of an internal unit may be expected occasionally to dominate its presence.

Cultures of Uredineæ in 1908: Professor J. C. ARTHUR, Purdue University.

For the tenth consecutive season cultures of various species of rusts have been made from both resting or winter spores and active or summer spores. There were 204 collections with resting spores available, of which, however, only 105 collections were brought into germinating condition. Of those which could be made to germinate 248 sowings were made, representing about 44 different species. Of collections with active spores 73 sowings were made, representing about 16 species. The proportion of successful cultures equaled, or possibly exceeded, that of previous seasons. Some of the results of most general interest may be mentioned. For the first time in America the early or brown rust on rye was grown on *Anchusa*, being sown in July, and the similar rust on wheat failed to germinate so soon after maturity, seemingly settling the much-discussed identity of the so-called *Puccinia dispersa* of Europe and of America. Many trials with the rust on timothy, *P. phleipratensis*, failed to infect barberry plants, this agreeing with European studies. Telial connections were established for *Eoidium macrosporum* on *Smilax*, and the æcia on *Ranunculus*, *Cymbalaria* and *Aquilegia* sp. An unusually large addition to current information was secured regarding species of *Gymnosporangium*. The life-cycle was demonstrated for the first time for one species from the southern states, one species from the northern states and one species from the western states beyond the Rocky Mountains.

Dichotoladium, a New Genus of the Mucorinæ:

Professor A. F. BLAKESLEE, Connecticut Agricultural College.

The species (*D. stoloniferum*) which forms the type of this genus was found five years ago in Venezuela growing saprophytically on dung. It has the habit of growth of a *Chaetocladium*, to which it is undoubtedly most nearly related. It differs from *Chaetocladium* primarily in that the fertile branches are dichotomous, not in whorls, and the sterile ends are not bristle pointed.

The genus may be briefly characterized as follows: Vegetative hyphæ stout, distinct, continuous. Fertile hyphæ erect or creeping, stoloniferous, bearing one to several lateral bushy crowns of repeatedly forked hyphæ. Ultimate branches of crown, slender, projecting beyond its surface, or short, terminated by persistent swollen heads upon

which are borne solitary spores. Sexual condition heterothallic.

The Interpretation of pre-Persoonian Names, and their Bearing on the Selection of a Starting Point for Mycological Nomenclature: Dr. E. J. DUBAND, Cornell University.

The paper discusses with quotations and examples the difficulties attending the interpretation of the species of pre-Persoonian authors because (1) the species were based entirely on external characters; (2) specific limits are now much more closely drawn than formerly; (3) microscopic characters, then ignored, are now regarded as the most important bases for generic and specific distinction, and (4) they as a rule preserved no specimens by which their names can be definitely determined. It is proposed, therefore, that the date 1753 be abandoned as the beginning of mycological nomenclature and a later one selected, so that these old names may be excluded. The considerations which should have weight in the selection of such a date are then taken up, and a brief history of systematic mycology given, with the discussion of several possible starting points. The conclusion is finally reached that Persoon's "Synopsis Methodica Fungorum," of 1801, be selected for the following reasons:

1. The genera and species described before the time of Persoon should be excluded from consideration because the majority of them can never be definitely and accurately identified.

2. Any publication in the modern period is too recent, the bulk of the systematic work having been done before it began.

3. Its date of publication is early enough to include a great majority of the published names of fungi, and nearly all of those which can be certainly fixed at the present time.

4. Its publication marks the beginning of the second important epoch in mycological history.

5. Its author was the originator of systematic mycology.

6. It can be used as well as any other work as the common point of departure for all groups of fungi.

7. It is a comprehensive work covering all groups of fungi, and summarizes what had been done before its time, so that it bears about the same relation to the classification of fungi that the "Species Plantarum" of Linnæus does to that of vascular plants.

8. Persoon's herbarium is in existence and is available for study, so that most of his names can be fixed with a degree of definiteness impossible for those before his time.

Adaptations in a Desert Lichen Flora: Professor BRUCE FINK, Miami University. By title.

Successful Inoculations with Peridermium: GEORGE GRANT HEDGCOCK, Bureau of Plant Industry.

Studies of the Potato Fungus, Phytophthora infestans: Professor L. R. JONES and Mr. N. J. GIDDINGS, University of Vermont.

Phytophthora infestans has been carried continuously in pure culture in the laboratories of the University of Vermont for four years. Starting with sterile blocks of raw potato, other culture media have been used with varying success, including raw and cooked potato and pumpkin; potato extract media, including juice from raw potato variously handled, potato broth, and broth with agar or gelatin; pumpkin agar; and several synthetic media solidified with agar.

Longevity.—Sealed gelatin cultures seven months old remained alive, but were slow in starting.

Noteworthy Morphological Characters Observed.—Haustoria-like branches in potato tissue as described by Delacroix. Abundant septation in old cultures. Apparent differentiation in some cases into two strains, the one exceeding the other in vegetative vigor. Oogonia-like bodies sparingly produced on certain media, frequent on others.

Concerning Infection and Disease Resistance.—Sporulation may occur in diseased tubers before digging and in storage. Infection occurs usually through eyes, but occasionally through wounds or lenticels. Wide differences occur between varieties (e. g., Early Rose, vs. Irene) as to ease of leaf infection and subsequent rate of spread; leading to conclusion that disease resistance of leaves may reside in mesophyll as well as possibly in epidermal tissues.

Similar differences occur in the rate of development upon sterile blocks cut from the interior of potato tubers, e. g., Ionia seedling vs. Irene. This difference is not due to the acid reaction of cell sap.

Artificial Cultures of Phytophthora with Special Reference to Oospores: Dr. G. P. CLINTON, Connecticut Agricultural Experiment Station.

In the 1905 Connecticut Agricultural Experiment Station Report the writer gave results of experiments with artificial cultures of *Phytophthora infestans*. The oospores, which are as yet unknown, did not develop in these. However, the oospores of *Phytophthora phaseoli*, described for the first time, readily developed in the cultures. The past fall specimens of the recently described

Phytophthora thaliotri were found, but cultures were not attempted, since the host had no perennial parts from which infected tissue could be taken. However, the oospores, not reported before, were found in the leaves. To account for their absence in the potato mildew, especially in artificial cultures, the writer suggested that these fungi may have distinct sexual mycelia. This is indicated by observations that the antheridia and oogonia of the other two species seem to be borne on separate mycelial threads. Recently the writer again obtained pure growths of the lima bean mildew, from which several hundred cultures have been made in an attempt to solve this problem. Cultures from mycelial growths, possibly mixed, have so far always produced oospores. Petrie dish separation cultures are now being made to get cultures from single spores. If the theory is correct, these should produce no oospores.

Origin and Function of the Peridium of the Rusts: Professor E. W. OLIVE, South Dakota State College. By title.

Observations on the Relation of Wound Parasites to the Heartwood of the Affected Tree: Dr. P. SPAULDING, Bureau of Plant Industry.

While studying various wood-rotting fungi for the past few years there has been noted a very apparent relation of the so-called "wound parasites" to the heartwood of the diseased trees. A very striking instance of this was that of *Fomes rubeus* occurring upon sassafras trees. In every case examined this fungus was found attacking the tree only in wounds where the heartwood was exposed by some injury, such as the breaking of a large branch, or the splitting of a branch from the main trunk. *Fomes ignarius*, as studied for the past four years, upon beech, has been found occurring in a similar manner. Hundreds of blazed beech trees have been examined, and in not a single instance was this fungus found growing upon these blazes in the sapwood. On the other hand, it was constantly found at wounds which extended into the heartwood. *Polystictus versicolor*, when attacking the heartwood of catalpa, occurs, growing into the stubs of dead branches. Such observations as have been thus far made upon *Fomes fraxinophilus* when attacking white ash show the same thing to be true, the attack practically always being made through dead stubs. Von Schrenk has also said that *Fomes rimosus* attacks the heartwood of black locust, either by entering through the dead stubs or through insect burrows. The sapwood of black locust is comparatively thin, and it is safe to accept his im-

plied statement that heartwood must be exposed before this fungus attacks its host.

Further Studies of the Anthracnoses: Dr. C. L. SHEAR and Miss ANNA K. WOOD, Bureau of Plant Industry.

Twenty-three forms of so-called *Colletotrichum* and *Glæosporium* from the following hosts have been studied since the writers' previous paper was published: 1, *Camellia japonica*; 2, *Caryota rumphii*; 3, *Cinnamomum zeylanicum*; 4, *Citrus vulgaris*; 5, *Citrus limonum*; 6, *Citrus decumana*; 7, *Citrus aurantium*; 8, *Coffea arabica*; 9, *Costus speciosa*; 10, *Cucurbita maxima*; 11, *Curculigo* sp.; 12, *Eriobotrya japonica*; 13, *Ficus longifolia*; 14, *Kentia* sp.; 15, *Lathyrus odoratus*; 16, *Ligustrum vulgare*; 17, *Maranta lineata*; 18, *Musa sapientum*; 19, *Persea gratissima*; 20, *Phormium tenax*; 21, *Piper macrophylla*; 22, *Pitcairnia corallina*; 23, *Psidium guajava*; 24, *Rubus occidentalis*; 25, *Thea bohea*.

Pure cultures made from conidia from hosts 6, 16, 19, 24 and 25 produced both conidia and ascospores and both these forms of fructification have been found on the host plants also. Cultures from conidia from hosts 3, 20 and 21 have produced both conidia and asci, but no ascogenous fructifications have been found on the host plants themselves. On hosts 1, 2, 5, 7, 8, 9, 11, 12, 13, 17, 22 and 23, both conidia and ascospores have been found. On hosts 4, 10, 14, 15 and 18 only conidia have been found and the cultures from the same hosts have produced only conidia.

Cultures from a single conidium taken from *Persea gratissima* carried through twenty-three generations have shown considerable variation in character of growth and development in different generations. Cultures from a single ascospore from the same source carried through seven generations have been quite uniform. The cultures from conidia usually produced an abundance of acervuli followed by perithecia. The cultures from ascospores produced no acervuli except a few very small ones in the first generation, but scattered conidia and an abundance of perithecia occurred in all. The ascospore cultures still produce conidia and the conidia cultures still produce asci.

No morphological characters either in cultures or under natural conditions have been found to be sufficiently constant to justify the segregation of species except perhaps in the case of the cotton anthracnose. The ripe rot fungus of the grape, *Glæosporium* (*Glomerella*) *rufomaculans*, represents fairly well the essential characters of all.

Cross inoculations from forms on fruits seem to indicate that the fungus may soon adapt itself to a different host and after a few generations develop about as readily on one fruit as another. All are perhaps only slightly specialized physiological forms of one omnivorous species.

A Bacterial Gall of the Daisy and its Relation to Gall Formations on Other Plants: Dr. C. O. TOWNSEND, Bureau of Plant Industry.

In 1904 some Paris daisy plants affected with galls of different sizes were received from a commercial grower of this plant in New Jersey. Work upon the cause of these gall formations and their relation to similar abnormal growths upon other plants was undertaken by the writer in cooperation with Dr. Erwin F. Smith, in charge of the Laboratory of Plant Pathology. Much of the technical work in connection with the problems investigated has been performed by Miss Nellie A. Brown, scientific assistant in the Laboratory of Sugar Beet Investigations.

After repeated efforts an organism was isolated from the galls, which had the ability to induce the formation of new galls upon healthy plants when inoculated into the stems and branches or even into the leaves of healthy daisy plants. From these galls formed by inoculation, the organism has been isolated and the process of inoculation repeated until no doubt remains regarding the cause of the gall formations.

The organism which produces these growths is a short rod, motile, possessing from one to three polar flagella, non-gas forming, and does not cloud bouillon heavily. On agar plate cultures the colonies come up slowly, usually in from three to five days, at a temperature of 25° C. The surface colonies are translucent white, round, with entire margins, smooth and dense. The growth is viscid on agar streak cultures after three days. The organism blues litmus milk, does not liquefy gelatin and does not grow at blood temperature in either agar or bouillon cultures. It will grow slightly at a temperature below 0° C.

The daisy organism will produce galls upon a large number of other plants, including tomato, potato, tobacco, sugar beet, hop, carnation, grape, raspberry, peach and apple. This work has led to the isolation of pathogenic Schizomycetes from the galls of peach, hard gall of apple, hairy root of apple, hop, rose and chestnut. The organisms obtained from the galls of these different plants are cross inoculable and are very similar, if not identical in size, shape, structure and habits of growth on media with the organism from the daisy gall. Pure cultures of these organisms are

now under investigation. The abnormal growths produced by inoculation with the organisms obtained from the galls of the plants mentioned are similar in many cases to those produced by the daisy organism upon those plants.

These investigations have left no doubt regarding the cause of the crown gall of the peach and at least some of the gall formations upon the apple and other economic plants.

Variation of Fungi Due to Environment: Professor F. L. STEVENS and Mr. J. G. HALL, North Carolina College of Agriculture and Mechanic Arts.

The effect of different densities of colonies on a plate is reported for five species of fungi, some of which show an entire elimination of pycnidial formation and the production of spores without covering when plates are thickly sown.

The effects of different densities of mycelium upon zone formation are illustrated from *Aecochyta* and *Sclerotinia*.

The effects of chemicals as influencing the color, growth and character of several species of fungi are reported. The changes produced are often sufficient to shift the fungus from one order to another.

The effect of light upon growth, spore formation and zonation of colonies, of several species of fungi is reported.

Under the heading of "unknown factors" several changes of character which could not be attributed to environment are mentioned.

DUNCAN S. JOHNSON,
Secretary

JOHNS HOPKINS UNIVERSITY

THE ASSOCIATION OF AMERICAN GEOGRAPHERS

THE fifth annual meeting was held in Baltimore, December 31, 1908, to January 2, 1909, under the presidency of Mr. G. K. Gilbert. Professor Albrecht Penck gave a lecture before the association at its opening session on Thursday evening, on "Man, Soil and Climate." Other features of the meeting were: the president's address by Mr. Gilbert, on the subject "Earthquake Forecasts," and a round table conference on "Geography for Secondary Schools," conducted by Professor R. E. Dodge. The conference was held informally in connection with a smoker at the Johns Hopkins Club on Friday evening. About thirty papers were read by members, representing meteorology and various phases of physiographic, biological, human and educational geography.

The important subject of cartography was also well represented. The officers for the ensuing year are:

President—W. M. Davis.

First Vice-president—L. A. Bauer.

Second Vice-president—E. R. Johnson.

Secretary—A. P. Brigham.

Treasurer—N. M. Fenneman.

Councilors—Cyrus C. Adams, R. S. Tarr and R. E. Dodge.

The place of the next meeting will be fixed by the council.

The following is a list of papers presented:

"Man, Soil and Climate" (public lecture), by Albrecht Penck.

"Earthquake Forecasts" (president's address), by G. K. Gilbert.

"Round Table Conference on Secondary Geography," by R. E. Dodge.

"Accumulation of Inherited Features in Shorelines of Evolution," by J. W. Goldthwaite.

"On the Elements of the Surface Sculptured by Glaciers," by W. H. Hobbs.

"Existing Glaciers of the Northern Hemisphere," by O. D. Von Engel.

"The Topographic A B C of Land Form," by F. E. Matthes.

"How May the Teaching of Geography in Elementary Schools be Improved?" by C. T. McFarlane.

"Apparatus for Instruction in the Interpretation of Maps," by W. H. Hobbs.

"Some Practical Results of the Ninth International Geographical Congress," by H. G. Bryant.

"Three Gatherings of Geographic Interest," by A. P. Brigham.

"Status of the Magnetic Survey of the Earth," by L. A. Bauer.

"A Reconnaissance in the Arctic Slope of Alaska," by E. D. Leffingwell.

"The Climate of Cuba," by H. Gannett.

"The Temperature at Great Heights above the American Continent," by A. L. Rotch.

"The Climate of the Historic Past," by E. Huntington.

"Origin of Civilization through Intermittency of Climatic Factors," by J. R. Smith.

"The National Forest Policy," by H. A. Smith.

"Some Results of the Recent Census in Cuba," by H. Gannett.

"The Anthropography of Some Great Cities," by Mark Jefferson.

"The Capacity of the United States for Population," by A. P. Brigham.

"Geographical and other Influences affecting

the Pottery Industry of Trenton, N. J.," by R. H. Whitbeck.

"Geographical Influences in the Development of Ohio," by F. Carney.

"Trade Routes in the Economic Geography of Bolivia," by I. Bowman.

"The Influence of the Precious Metals on American Exploration, Discovery, Conquest and Possession," by G. D. Hubbard.

"The Stream Robbery on which the Belle Fourche Reclamation Project is Based," by N. H. Darton.

"A Remarkable Glacial River and its Modern Representative," by F. Taylor.

"Delta Form and Structure of the Thames River Terraces, Connecticut," by F. P. Gulliver.

"The Requisites of a School Wall Map," by J. P. Goode.

A. P. BRIGHAM,
Secretary

THE SOCIETY FOR HORTICULTURAL SCIENCE

At a business meeting of the society held in Baltimore, December 31, 1908, several important questions were discussed. The committee appointed at the Jamestown meeting to interview the Secretary of Agriculture with reference to having the annual reports of the society published by the Department of Agriculture reported that they had interviewed Dr. B. T. Galloway, who represented the Secretary of Agriculture in this matter, and that it was almost certain that the department would publish the reports, provided the following amendments were adopted by the society:

"That the association shall be known as the American Association of Official Horticulturists, the object of which is to promote the science of horticulture, and that any person connected with a state or federal experiment station or with the U. S. Department of Agriculture or its territorial stations, or with any other institution in the United States or Canada, who is engaged in the teaching of horticulture, or in experiments bearing upon it, may become a member of the association and shall be entitled to vote on the conditions which are embodied in the present constitution. Furthermore, that all horticulturists in the United States and in Canada, or in any other country engaged in the teaching or investigation of horticulture, may become associate members of the association under the same conditions that govern the admission of members and shall have all the privileges of members except the right to vote and hold office."

These amendments were discussed and were satisfactory to the members present, but the amendments could not be adopted, since the by-laws require that amendments presented at one meeting can not be adopted before the next annual meeting.

It was the sentiment of the society to affiliate with the National Association for the Advancement of Agricultural Science when the organization of the latter society was sufficiently advanced to make this possible and desirable.

The society voted to fix a price of one dollar per copy for its annual reports to new members and to educational institutions, and a price of two dollars per copy to non-members.

The officers and members of committees for 1908 were reelected for 1909.

C. P. CLOSE,
Secretary-treasurer

SOCIETIES AND ACADEMIES

THE KANSAS ACADEMY OF SCIENCE

THE forty-first annual meeting of the academy was held in Topeka during holiday week, and was of unusual interest both in the quality and number of papers presented for discussion. The retiring president, E. Haworth, chose for the subject of his address "The Life History of a River," and discussed the cause of floods, and the means of controlling these destructive agencies. A. J. Smith told how the city of Emporia is securing a good water supply from the underflow of the Neosho river. The pure food and drugs law called forth several important papers from Professors Bailey, Sayre, Willard, Zieffle and Jackson. The biologists reported additions made in the past year to the lists of birds, mammals and insects. Professor Dyche contributed important notes of his experience in preserving the skins of mammals. Dr. Williston sent a paper on the "Skull Structure of *Diplocaulus*" with restoration, and C. H. Sternberg, the enthusiastic fossil hunter, gave an account of his last summer's finds in the Laramie beds of Wyoming.

One evening was given to memorial exercises in honor of the late Dr. Francis Huntington Snow, one of the founders of this academy, and for more than forty years connected with the University of Kansas, where he held the office of chancellor for twelve years. One of his earliest colleagues, Professor E. Miller, gave a memorial address, and other members spoke of him as a collector, teacher and contributor to scientific discovery. Another evening session, held in Washburn College, was in

part a social occasion, and was otherwise made interesting by Professor Edmondson giving some excellent stereopticon views illustrating an account of his last summer's trip to Tahiti. Professor Parker gave some fine specimens of bird photography, and Professor Sternberg exhibited some good views of the Laramie beds of Wyoming.

The officers elected for the ensuing year were as follows:

President—F. B. Dains, Topeka.

First Vice-president—J. M. McWharf, Ottawa.

Second Vice-president—A. J. Smith, Emporia.

Treasurer—F. W. Bushong, Lawrence.

Secretary—J. T. Lovewell, Topeka.

Ottawa was selected as place for the next annual meeting.

The following papers were presented:

Papers, illustrated by stereopticon:

"Some Glimpses of Tahiti," by C. F. Edmondson.

"Notes on Photography of Wild Birds," by J. B. Parker.

Chemical and Physical Papers

"Resins in Vanilla Extract," by H. L. Jackson.

"An Examination of Apparatus for a Simple Determination of Carbon Dioxid in Air," by E. H. S. Bailey.

"Sulphites as Preservatives," by Edith A. Goodwin and E. H. S. Bailey.

"The Character of the Mid-continent Petroleum," by F. W. Bushong.

"Fluctuations in the Mineral Contents of the Kaw River," by F. W. Bushong and A. J. Weith.

"The Importance of Pharmacological Methods in Drug Assay," by Adolph Zieffle.

"Suggested Legislation in Regard to the Selling of Cocaine," by H. W. Emerson.

"Enameling Steel," by R. D. Landrum.

"The Relation of Manganese to the Corrosion of Iron," by H. P. Cady.

"Progress of Work in Drug Analysis under Pure Food and Drugs Law," by L. E. Sayre.

"Comments on Analysis of Spices," by L. E. Sayre.

"Study of the Cause of Coal-mine Explosions," by E. Haworth and C. M. Young.

"The Medullary Ray as an Element of Strength in Structural Timber," by F. E. Jones.

"On some Methylenic Derivatives," by F. B. Dains.

"Recent Investigations of the Properties of Steam," by P. F. Walker.

"Pelton Water-wheel Test made at the University of Wisconsin in the Summer of 1908," by Chas. I. Corp.

"Some Notes on the Steel-hardening Minerals," by J. C. Cooper.

"A Speculation in Crystallography," by J. E. Todd.

"Economy of Heat in Cooking," by J. T. Lovewell.

"Some Difficulties in Testing Food for Sulphites," by J. T. Willard and C. A. A. Utt.

Geological Papers

"Some Notes on the Olympic Peninsula, Washington," by A. B. Reagan.

"The Formations of the Marlon Stage of the Permian," by J. W. Beede.

"Why the Southern Hemisphere is the Principal Water Hemisphere and the Northern the Principal Land Hemisphere," by J. J. Jewett.

"The Drainage of the Kansas Ice Sheet," by J. E. Todd.

"Expedition to the Laramie Beds of Converse County, Wyoming, 1908," by C. H. Sternberg.

"A Study of Certain Features of the Lawrence Shales," by J. A. Yates.

"The Extremities and Skull Structure of *Diplocaulus*, with Restoration," by S. W. Williston.

"The Skull Structure of *Diplocaulus magnicornis* Cope," by R. L. Moodie.

"Carboniferous Quadrupeds of Kansas," by R. L. Moodie.

Biological Papers

"A New Bird for the Kansas List, taken at Lawrence," by L. L. Dyche.

"Supplementary Additions to the List of Kansas Diptera," by E. S. Tucker.

"Weismann's Germ Plasm Hypothesis Untenable," by L. C. Wooster.

"Notes on a Captive *Heloderma*," by B. B. Smyth.

"The Birds of the Olympic Peninsula, Washington," by A. B. Reagan.

"Trees and Shrubs of Kansas," B. B. Smyth.

"Distribution, Natural Enemies and Breeding Habits of the Kansas Pocket Gophers," by T. H. Scheffer.

"The Poison Glands of a Rattlesnake during the Period of Hibernation," by L. L. Dyche.

"Notes on Bats," by Lumina C. R. Smyth.

"The Latest Tests for Gas-forming Bacteria in Water," by W. B. Wilson.

"Additions to the List of Kansas Coleoptera," by W. Knaus.

"Some Notes on Kansas Coleoptera," by W. Knaus.

"Note on the Northern Distribution of *Amblychila cylindriciformis* Say," by W. Knaus.

"Kansas Coleoptera of the Families Colydiidae,

Cucujidae, Cryptophagidae, Mycetophagidae, Dermestidae, Histeridae, Nitidulidae, Lathridiidae, Trogoxetidae, Parnidae, Heteroceridae, Dasytylidae and Rhipiceridae," by W. Knaus.

"Intercellular Spaces in Plants," by L. A. Kenoyer.

"Some Notes on the Common Mole," by T. H. Scheffer.

"Coccidae of Kansas," by G. A. Dean.

"Notes on Kansas Mammals," by D. E. Lantz.

"Some Interrelations of Protozoa," by C. H. Edmondson.

"List of Insect Types and Co-types in the Collection of the University of Kansas," by C. H. Withington.

"Habits of Parasitic Hymenoptera, II.," by C. H. Withington.

Miscellaneous Papers

"The Importance of having Standard Weights and Measures," by E. F. Stimpson.

"Temporary Industrial Fellowships," by R. E. Duncan.

"Railway Rates from an Engineering Standpoint," by B. F. Dalton.

"The Centenary of Charles Darwin," by A. H. Thompson.

"Estimation of the Relative Value of Feeds," by E. B. Cowgill.

"Further Notes on the Influence of Heredity in Stock-breeding," by I. D. Graham.

"Ups and Downs of our Homes from an Architect's Point of View," by N. P. Nielsen.

"Some Glimpses of Tahiti," by C. H. Edmondson.

"Cancer," by J. M. McWharf.

"The Cause and Prevention of Tuberculosis," by S. C. Emley.

"An Improved Water-supply for the City of Emporia," by A. J. Smith.

"A Speculation in Crystallography," by J. E. Todd.

"Indian Remains in the Canadian River Valley," by T. L. Eyerly.

"Notes on Photography of Wild Birds," by J. B. Parker.

"A New Geometrical Figure and its Possible Application," by E. C. Warfel.

"Preliminary Note on Measuring the Speed of Photographic Shutters," by H. I. Woods.

"Views and Notes from Utah," by I. D. Cardiff.

THE ASSOCIATION OF TEACHERS OF MATHEMATICS IN THE MIDDLE STATES AND MARYLAND

THE eleventh meeting of the Association of

Teachers of Mathematics in the Middle States and Maryland was held at Franklin and Marshall College, Lancaster, Pa., on November 28. After the address of welcome by President Stahr, the following papers were read:

"Training versus Facts," by William Henry Metzler, Syracuse University.

"Elementary Logic as a Basis for Plane Geometry," by Eugene Randolph Smith, Polytechnic Preparatory School, Brooklyn, N. Y.

"The International Commission on the Teaching of Mathematics," by David Eugene Smith, Teachers College, New York City.

"Checks, Their Use and Abuse," by William E. Breckenridge, Stuyvesant High School, New York City.

"Historical Mathematical Material from the East," by Miss Bertha L. Broomell, Teachers College, New York City.

The annual election of officers was held; the officers elected follow:

President—William Henry Maltbie, Woman's College, Baltimore, Md.

Vice-president—William E. Breckenridge, Stuyvesant High School, New York City.

Secretary—Eugene Randolph Smith, Polytechnic Preparatory School, Brooklyn, N. Y.

Treasurer—Emma Hazleton Carroll, High School for Girls, Philadelphia, Pa.

Members of the Council—William H. Metzler, Syracuse University; Susan C. Lodge, Philadelphia Collegiate Institute for Girls.

The council appointed ten delegates to the American Federation, a committee on publication, composed of William H. Metzler, *chairman*, Eugene R. Smith, Jonathan T. Rorer, and a committee on mathematical work in continuation schools, having as chairman William E. Breckenridge.

The following amendment to the constitution was recommended by the council:

Paragraph I. of Section II., to read:

"The annual meeting shall be held at a time and place to be selected by the council."

The spring meeting of the association will be held at Syracuse University on Easter Saturday.

EUGENE R. SMITH,
Secretary.

THE BIOLOGICAL SOCIETY OF WASHINGTON

THE 452d meeting was held January 9, 1909, with President Palmer in the chair. The following papers were presented:

The Type of the Genus Cactus: J. N. ROSE.

Present Status of the Cotton Boll Weevil: W. D. HUNTER.

The speaker discussed especially two of the most important biological questions that have arisen on account of the invasion of the cotton belt by the boll weevil. These questions are, first, the extent to which the insect is capable of adapting itself to the conditions of this country which are radically different from those of the original home, and, second, the effect on the indigenous fauna in this country.

The wide variation in rainfall, geological formation and other respects in areas that have been invaded was described. The rainfall varies from 12 to 50 inches; the elevation from sea level to 2,500 feet, the absolute minimum temperature from -20° F. to $+20^{\circ}$ F. These variations have caused distinct agricultural provinces to arise, and, indeed, have been so important that they have had an effect towards establishing races of men. The weevil has maintained itself in all this region, but has been most affected by dryness. The cotton plant has an advantage over the weevil in this respect, which indicates that cotton production in western Texas is certain to increase enormously. It is not too much to suppose that the increase in that quarter will offset the falling off in other parts of the belt.

The boll weevil has had very important effects upon the local insect fauna. A number of parasitic and predaceous insects have changed from the original indigenous hosts to the immigrant. Eight predaceous forms attack the adult, 15 similar forms attack the larva, 24 hymenopterous parasites also attack the larva. These parasites also attack 48 species of weevils. The boll weevil complex, therefore, comprises 49 weevils which feed upon 95 plants and 97 insect enemies of these weevils. The interrelationship is so intimate that a factor that will affect any one of the 95 plants in the complex may react upon the boll weevil.

It was pointed out that the boll weevil problem has recently taken on entirely new aspects in the Mississippi Valley. The heavy precipitation, abundance of timber and poor drainage have caused the problem to be much more serious than it was in Texas. This has been shown during the season of 1908 by a great falling off in the production of cotton in Louisiana and the infested portion of Mississippi.

The best hope for the future is in the insect enemies of the weevil. The climatic conditions in Texas that have checked the weevil have also checked the parasites. With the removal of these

checks in the Mississippi Valley it is supposed that the efficiency of the parasites will be proportionately much greater than it has been elsewhere. Practical experiments have been conducted which show that the artificial introduction of parasites that have adopted themselves to the boll weevil in Texas is a hopeful line of assistance to the cotton planter.

Investigations of Toxoptera graminum and its Parasites: by F. M. WEBSTER.

This is a species of aphid which on account of its depredations has come to be known in the grain-growing sections of the southeast and southwest as the green bug. Invasions occur at irregular intervals both in this country and in Europe, when it breeds in immense swarms, not only proving exceedingly destructive, but the winged insects flying or drifting about in clouds, sometimes becoming troublesome to people.

It is known to occur in southern Europe, Hungary, Belgium, in Siberia and in the Orange River Colony, South Africa. In the United States it extends from Mexico and the Gulf northward to Canada, excepting in the central New England states. It also occurs on the Pacific coast. It inhabits elevations of only a few feet above the sea level to the high plateaus of the west at an elevation of eight thousand feet.

While preferring grain, especially oats, it breeds on the following grasses: *Poa pratensis*, which is a common food plant all over the north; *Alopecurus geniculatus*, *Agropyron occidentale* and *Hordeum pusillum* in Oklahoma, Kansas and Colorado; *Agropyron tenerum*, *Bromus portei*, *Elymus striatus*, *Hordeum caespitosum*, *Polypogon monspeliensis* and *Stipa viridula* in New Mexico; *Distichlis spicata* and *Hordeum jubatum* in Montana; *Setaria glauca* in Indiana; and *Dactylis glomeratus* in the northern states and Virginia. In the northern section of the country its principal food plant seems to be blue grass.

Its destructive outbreaks in the United States seem to be regulated by the mild winters and cold springs, not so much on account of the influence of temperature upon the insect itself as upon its principal parasite *Lysiphlebus tritici* which ordinarily holds it in check. Wintering over in the north in the egg stage; in the central portion of the country as far south at least as Tennessee and southern Kansas, both in the egg and as viviparous females; and as the male and sexual female of *Toxoptera graminum* may also occur in the spring, it seems quite possible that in the far south, in the region of the Rio Grande River, this aphid may

pass the dry season instead of the winter in the egg stage, although this has not yet been proved. While the egg-laying female is quite distinct from the viviparous female, individuals frequently occur that are both oviparous and viviparous. The oviparous female produces very few eggs, probably not to exceed a half dozen. The young hatching from these eggs are all of them viviparous females and in the north these continue to remain viviparous until fall and sometimes even through the entire winter.

The principal parasite, *Lysiphlebus tritici*, is parthenogenetic, the offspring of virgin females being usually all males. Occasionally there are females, and these being kept virgin have produced an occasional female to the third generation from the mated female. These parasites deposit their eggs singly in the body of the *Toxoptera*, and the larva when it becomes full grown lines the now empty body of its host with silken threads and attaches the cocoon to the leaf of the plant. These cocoons cause the body of the host to assume a rotund appearance and brownish color and where the insect is excessively abundant and the parasites increasing rapidly these brown bodies become so thick as to give a field of wheat or oats observed at a distance a brownish tinge.

Other insect enemies are the lady beetles, Coccinellidae, a minute *Aphelinus* and probably a larva of a small fly belonging to the genus *Leucopsis*.

M. C. MARSH,
Recording Secretary

THE NEW YORK ACADEMY OF SCIENCES. SECTION OF ASTRONOMY, PHYSICS AND CHEMISTRY

At a meeting held at the Museum of Natural History, on Monday, January 18, Dr. O. W. Willcox presented a paper entitled "Cylindrogenite, a Possible Representative of a Cylindrical (Non-Hauyan) Order of Crystals," in which he described a remarkable new form of limonite which occurs in the Red Bank sand of the Upper Cretaceous of New Jersey. The limonite, var. Cylindrogenite, occurs normally as perfect cylinders (which may be either hollow or solid), terminated at either end by a cone or a hemisphere. Two or more cylinders frequently intergrow, forming aggregates in which each cylinder preserves the alignment of its own axis; a number of such aggregates and also a number of photographs were exhibited. A most careful and painstaking study extending over more than three years having failed to suggest any other possible origin for these

objects, Dr. Willcox makes the novel suggestion that they are representatives of a non-Hauyan order of crystals, which he proposes to call the cylindrical system, as distinguished from the cubical and other systems of the Hauyan order. The speaker pointed out that there are no *a priori* reasons for regarding the Hauyan order as the sole mode of expression of crystalline nature; he knew of no reason why nature should be regarded as impotent to fashion a crystal after the form of a cylinder as well as after the form of a cube. As the facts indicate that the cylinders were formed by molecules of dissolved matter in the act of separating from solution to constitute the solid phase, and in so doing assumed a geometrical form of consistent regularity, they are as much entitled to be regarded as crystals as are the cubes which are formed when sodium chloride separates from solution. The cylinder being a geometrical form of higher symmetry than the cube, the absence of distinguishing crystallographic characters as seen under the microscope would be accounted for; and hence a crystallographic investigation shows nothing out of the ordinary.

Professor D. W. Hering read a paper on "Orthopedic Photography, Notes on the Rectification of Distorted Pictures." The paper discussed the defects common in kodak pictures, which arise from badly timed exposure in various conditions of light, followed by development of a whole set of films at once, resulting in excessive inequalities of light and shade. In printing from such a negative, if the source of light is small, as a gas flame or incandescent bulb, these faults can be corrected to a great extent by holding the printing frame in such a position that the distance to different parts of the negative gives different intensity of illumination, and the subsequent development of the print is normal. It also considered the distortion of pictures arising from using a short focus lens, and holding the camera at an awkward angle, as, for instance, pointing it upward or downward at a considerable inclination. By re-photographing the distorted picture, placing it before the camera at an angle to the axis of the lens, a counter distortion is effected which under judicious management rectifies the picture and sometimes improves it. The discussion was directed entirely to correction of defects by physical treatment instead of chemical. Numerous lantern slides illustrated the various stages of these corrective processes.

Professor W. Campbell read "Some Notes on Western Smelters." A series of lantern slides intended to show the evolution of the western

lead smelters on account of changes in conditions and improvements in practise. A photograph of the Globe Smelter, Denver, showed the location of the main buildings. A plan of the plant showed the receiving tracks, bins for fuel, fluxes and ore, the beds, the various roasters, the blast-furnaces and the matte settling reverberatories, fines, bag-house, the old refinery, etc. A tree of smelting showed the course of the materials. Other slides showed the handling of raw materials, the methods of bedding at different plants; of roasting, briquetting of fines; the blast-furnace, types, methods of charging, tapping of lead, of matte and slag, the separation of the same, handling of foul slag, etc. Level versus sloping sites shown by contrasting photographs of the Murray plant with those of the Leadville, Eilers, Pueblo, etc. Two copper smelters were described: the Highland Boy at Bingham, with 20 McDougall and 3 Wetthey roasters, 9 reverberatory smelters and 4 converter stands; the Garfield plant, with 2 blast-furnaces and 3 reverberatory smelters, 4 converter stands, the oxide and sulphide mills, beds, roasters, the Huntington-Herberlein equipment for roasting fine concentrates, etc.

W. CAMPBELL,
Secretary

COLUMBIA UNIVERSITY,
NEW YORK CITY

SECTION OF GEOLOGY AND MINERALOGY

At the regular meeting of December 7, 1908, the evening was devoted to the conditions and problems that have developed by tunneling the Hudson River gorge. Many engineers directly concerned in these enterprises or related ones were present and joined in the discussion.

The following three papers were read summarizing the accumulated data and suggesting the history and structure indicated by them.

"Our Knowledge of the Filled Channel of the Hudson in the Highlands and the Submerged Gorge on the Continental Shelf," by Professor J. F. Kemp. It was shown that the depth now known, over 650 feet, at Storm King Mountain, 50 miles above New York, is greater than at any other point in the whole drainage system except far out on the continental shelf.

"A Summary of an Investigation into the Structural Geology of Southern Manhattan and the Condition of the East River Channel," by Dr. Charles P. Berkey. The results of identification of material recovered from 300 drill borings in southern Manhattan and the adjacent channels

were shown. In this area there are no rock outcrops and nothing is known of bed rock type or condition except what can be determined in this way. It is now certain, however, that the southern end of the island is not wholly underlain by Manhattan schist as formerly mapped, but that the east side is made up of the usual succession of folded Fordham gneiss, Inwood limestone and Manhattan schist.

"Some of the Latest Results of Explorations in the Hudson River at New York City," by Dr. E. O. Hovey. Borings made by the Pennsylvania Tunnel Company across the Hudson on the line of Thirty-second Street were shown and interpreted. Bed rock has been penetrated at three points in the gorge proper. All are approximately 300 feet deep to rock. But since these holes are nearly 1,200 feet apart, the interesting question of a possible narrow inner gorge still remains. Seeing that the proved depth in the Highlands is at least 350 feet deeper than is yet found at New York City, the Hudson problem may still be considered an open one.

CHARLES P. BERKEY,
Secretary of Section

THE AMERICAN CHEMICAL SOCIETY
NORTHEASTERN SECTION

THE eighty-eighth regular meeting of the section was held on December 18, at the Chemical Laboratory of Harvard College, Cambridge. An address upon "The Systematic Relations of the Compressibilities of Elements and Simple Compounds" was delivered by Professor Theodore W. Richards, of Harvard University. The speaker called attention to probable relationships between the compressibilities of the elements, the changes of atomic volumes upon the formation of compounds, and the chemical affinities as measured by heats of reaction. After pointing out the lack of reliable data concerning the compressibility of substances, he described the apparatus in use by himself for the determination of this constant and stated that values for the compressibility of thirty-five elements and a number of compounds had already been obtained. It was shown that the compressibility is a periodic function of the elements and that the relationships with atomic volumes and heats of reaction are in remarkable agreement with the predictions. Some striking relationships among organic compounds were cited and it was stated that further work is being done upon the study of isomers.

Professor Bertram B. Boltwood, of Yale Univer-

sity, briefly described the recent work of Professor Rutherford upon the "α rays."

THE eighty-ninth regular meeting of the section was held at the Massachusetts Institute of Technology on January 22. The following papers were presented: "Fundamental Principles underlying the Decay of Structural Materials," by Professor W. H. Walker, of the Massachusetts Institute of Technology, a concise statement of the electrolytic theory of the corrosion of iron; "Protective Coatings for the Conservation of Structural Materials," by Mr. Robert S. Perry, president of the scientific section of the Paint Manufacture Association of the United States, an account of work being done in testing the porosity and elastic strength of paint skins and the inhibitive or stimulative effect of certain pigments on the rate of corrosion of metals.

KENNETH L. MARK,
Secretary

THE SCIENTIFIC ASSOCIATION OF JOHNS HOPKINS
UNIVERSITY

THE association held its monthly meeting January 13, when it was addressed by Professors J. M. Baldwin and J. B. Whitehead.

Professor Baldwin spoke upon the subject of "Genetic Science," classifying sciences as genetic or agenetic. He showed the ground for the distinction between them to be that they are qualitative and quantitative, respectively.

The limitations of quantitative science were pointed out while recent advances in the scientific and philosophical theory of genetic science were discussed. Quantity and quality both represent special points of view, each requiring a certain abstraction and limitation with respect to the actual events of nature. It is the task of philosophy to affect the synthesis which will not disqualify either.

Professor Whitehead discussed the problem of the "Electrification of Steam Railways." Steam railways are being transformed and operated electrically in tunnels in order to secure freedom from gases due to combustion; in terminals to increase traffic capacity, and on through service in order to lessen cost of operation. Coal consumption and cost of repairs are lessened. It was shown that the electrification of all the steam railways of the country would lessen the total consumption of coal of the country about 7 per cent.

RECENT PROGRESS IN AERONAUTICS¹

THERE are two general classes of vehicles of the air, (a) those which depend for their support upon the buoyancy of some gas lighter than air, and (b) those which depend for such support upon the dynamic reaction of the air itself. These classes are designated:

(a) Lighter-than-air types:

Free balloons, dirigible balloons or airships.

(b) Heavier-than-air types:

Aeroplanes, orthopters, helicopters, etc.

It should be remarked, however, that these two general classes exhibit a growing tendency to overlap each other. For example, the latest dirigible balloons are partly operated by means of aeroplane surfaces, and are also often balanced so as to be slightly heavier than the air in which they move, employing the propeller thrust and rudder surfaces to control the altitude.

I. AEROSTATION

Captive and free balloons, with the necessary apparatus and devices for operating the same, have been for many years considered an essential part of the military establishment of every first-class power. They played a conspicuous part in the siege of Paris, and were often valuable in our own civil war. The construction and operation of aerostats are too well understood to need further attention here.

Although many aerodynamic data are needed for the proper design of a dirigible

¹ Abstract of an address before Section D—Mechanical Science and Engineering—American Association for the Advancement of Science, Baltimore, 1908.

airship, yet the experience already available in the construction and performance of such ships built on different plans is sufficient to enable the engineer to proceed with the design of a dirigible balloon to accomplish definite results along fairly accurate lines. In the case of this class of lighter-than-air ships the following general equation obtains:

$$W - w = V(\sigma - \sigma/n)$$

where

W = weight of balloon, envelope, car and aeronauts,

V = volume of balloon,

σ = density of the air,

n = density of air as compared with gas,

w = weight of air displaced by car and aeronauts and envelope of balloon.

If we call the weight of the gas in the balloon M , then we can write this equation in the following manner:

$$W + M = w + nM,$$

from which we find that

$$M = (W - w/n - 1)$$

and

$$V = [(W - w)/\sigma] [n/(n - 1)],$$

thus obtaining the volume of gas required. If the volume of the gas-bag, car, aeronauts, etc. = v , then $w = v\sigma$; so that the preceding equation may be written

$$V = [(W - v\sigma)/\sigma] [n/(n - 1)].$$

Thus far, certainly, no dirigible balloon has ever been developed which has attained an independent speed greater than forty miles per hour. It will readily be admitted that an airship so designed as to reach a speed of fifty or sixty miles per hour would be regarded as a most decided step forward in the art, since this difference of velocity is just the increment needed to place such craft on a practical basis capable of maneuvering in the air in all ordinary weather. This advancement, although requiring much

consideration, would fully compensate in practical results.

The first point to be decided upon in the design of an airship is the method of maintaining the shape of the gas-bag against the pressure encountered at the maximum velocity to be attained. There are two schools of design in this respect, each having its adherents. One maintains the shape of the gas-bag by a rigid interior frame, and the other by means of the internal pressure of the gas itself.

Upon the selection of the type depends to a large extent the particular shape of the envelope. If the envelope is to maintain its shape by interior pressure of gas, evidently it must be so designed that the maximum pressure of the air developed at the speed contemplated shall not be sufficient to cause deformation of any part of the envelope. This can be effected only by making the uniform internal pressure at least equal to the maximum external pressure. Since the maximum external pressure occurs over the prow of the airship, this, evidently, is the particular part which must receive most careful attention with this system.

The desirable shape of head would evidently be one where the distribution of external pressure due to air resistance at the velocity used is uniform. In addition to preventing deformation of the gas-bag, a prime requisite also is that the shape shall be such that the total resistance, comprising head resistance and skin-friction, shall be a minimum for a given displacement and velocity.

This immediately forces the question of the law of resistance of the air. On this subject there are numerous aerodynamic data for low velocities, and also for very high velocities, but such data are incomplete for the range of velocities here considered.

In fact, the law of resistance of the air

for surfaces of revolution as experimentally determined, is known to vary not with any constant power of the velocity, but by a range of exponents from the first to the cube, if not higher. For example, in the enormous velocities attained by modern artillery, where bodies weighing a ton or more are hurled through the air at 2,000 feet per second, it is known that the physical phenomena become entirely different in nature from those found when dealing with moderate velocities such as are met in transportation devices.

If the rigid system be employed where an internal frame prevents deformation of the envelope, the stresses due to external pressure are taken up by the framework itself, and the gas required for flotation is usually contained in several separate receptacles or ballonets similar to compartments employed in ships. In this system, therefore, we are concerned only in securing such a shape of the rigid frame as will fulfill the condition of minimum total resistance for a given displacement and velocity.

Once the shape of the bag is determined from the considerations already enumerated, the dimensions become immediately fixed when the tonnage is assumed, or conversely, if any linear dimension is assigned the tonnage is thereby determined.

In addition to the two general systems above considered, there are various types involving some of the principles of each, which are classed in general as semi-rigid systems. Such systems usually comprise a rigid frame, to which is attached the gas-bag above, and the load below.

The next step is one of structural design along strictly engineering lines. The aerodynamic features of airship construction may be considered under the heads: (a) static balance, (b) dynamic balance, (c) stability, (d) natural period and oscillation.

Static Balance.—The dimensions of the

gas-bag being determined, the lift of each transverse segment thereof is immediately known, and the design of the frame may proceed by approximate trial and correction as in other structural work. The weight of each segment of the envelope itself is readily computed, which, added to the corresponding segment of the frame, gives the total weight of each segment, and this total subtracted from the lift of each segment gives the net lift for that complete segment. From the magnitude and position of these net forces the position of the resultant lift is known, and this determines the vertical line through the center of gravity. Such procedure evidently insures static balance of the machine as a whole, and an approximate distribution of the load.

Dynamic Balance.—The dynamic balance must also be carefully considered; and here a difficulty has been experienced on account of the inability to place the resultant thrust coincident with the line of resistance of the ship as a whole. Heretofore, it has been customary to balance the thrust-resistance couple by means of suitable horizontal rudders or planes, so situated and at such angles that the resultant moment of the system should be zero at uniform speeds of travel, though not necessarily zero for accelerated motion.

If, however, the line of thrust be made coincident with the line of resistance, the disturbing moment in question will be eliminated at uniform speeds. If, furthermore, the center of mass be located on the line of thrust and sufficiently forward to form a righting couple with the resistance when the wind suddenly veers, the evil effects of a disturbing moment will be obviated for variable as well as for constant speeds. The ship is then dynamically balanced.

This, of course, requires that the form of hull be such that a quartering wind shall exert a force passing to the rear of the

center of mass. To illustrate, a good example of dynamic balance is found in a submarine torpedo, or a fish.

Stability.—The foregoing adjustments still allow the center of mass to be placed below the center of buoyancy. This is a provision that is important in aeronautics as well as in marine architecture; indeed, it is the only practical provision for keeping an even keel and preventing heeling when the ship is at rest, or simply drifting with the wind. If the center of gravity be well below the center of buoyancy, the vessel is proportionately stable, but, of course, the stability is pendular, and may admit of considerable rolling and pitching due to shifting loads, sudden gusts of wind, etc., unless special devices be used to dampen or prevent these effects.

Natural Period and Oscillations.—It may happen also that the equilibrium of the ship is disturbed by periodic forces whose periods are simply related to the natural period of the ship itself. In this case the oscillations will be cumulative and may become very large. Such effects are well known to marine engineers, and may be treated as in ordinary ship design.

II. AVIATION

This division comprises all those forms of heavier-than-air flying-machines which depend for their support upon the dynamic reaction of the atmosphere. There are several subdivisions of this class dependent upon the particular principle of operation. Among these may be mentioned the aeroplane, orthopter, helicopter, etc. The only one of these that has been sufficiently developed at present to carry a man in practical flight is the aeroplane. There have been a large number of types of aeroplanes tested with more or less success and of these the following are selected for illustration.

The design of an aeroplane may be considered under the heads of support, resist-

ance and propulsion, stability and control.

Support.—In this class of flying-machines, since the buoyancy is practically insignificant, support must be obtained from the dynamic reaction of the atmosphere itself. In its simplest form, an aeroplane may be considered as a single plane surface moving through the air. The law of pressure on such a surface has been determined and may be expressed as follows:

$$P = 2k\sigma A V^2 \sin \alpha,$$

in which P is the normal pressure upon the plane, k is a constant of figure, σ the density of the air, A is the area of the plane, V the relative velocity of translation of the plane through the air, and α the angle of flight.

This is the form taken by Duchemin's formula for small angles of flight such as are usually employed in practise. The equation shows that the upward pressure on the plane varies directly with the area of the plane, with the sine of the angle of flight, with the density of the air, and also with the square of the velocity of translation.

It is evident that the total upward pressure developed must be at least equal to the weight of the plane and its load, in order to support the system. If P is greater than the weight the machine will ascend, if less, it will descend.

The constant k depends only upon the shape and aspect of the plane, and should be determined by experiment. For example, with a plane 1 foot square $k\sigma = 0.00167$, as determined by Langley, when P is expressed in pounds per square foot, and V in feet per second.

The first equation may be written

$$AV^2 = P/2k\sigma \sin \alpha.$$

If P and α are kept constant then the equation has the form

$$AV^2 = \text{constant}.$$

An interpretation of the second equation reveals interesting relations. The supporting area varies inversely as the square of the velocity. For example, in the Wright aeroplane, the supporting area at 40 miles per hour is 500 square feet, while if the speed is increased to 60 miles per hour this area need be only $500/1.52 = 222$ square feet, or less than one half of its present size. At 80 miles per hour the area would be reduced to 125 square feet, and at 100 miles per hour only 80 square feet of supporting area is required. These relations are conveniently exhibited graphically.

It thus appears that if the angle of flight be kept constant in the Wright aeroplane, while the speed is increased to one hundred miles per hour, we may picture a machine which has a total supporting area of 80 square feet, or a double surface each measuring about $2\frac{1}{2}$ by 16 feet, or 4 by 10 feet if preferred. Furthermore, the discarded mass of the 420 square feet of the original supporting surface may be added to the weight of the motor and propellers in the design of a reduced aeroplane, since in this discussion the total mass is assumed constant at 1,000 pounds.

In the case of a bird's flight, its wing surface is "reefed" as its velocity is increased, which instinctive action serves to reduce its head resistance and skin-frictional area, and the consequent power required for a particular speed.

Determination of k for Arched Surfaces.

—Since arched surfaces are now commonly used in aeroplane construction, and as the first equation applies to plane surfaces only, it is important to determine experimentally the value of the coefficient of figure k , for each type of arched surface employed, especially as k is shown in some cases to vary with the angle of flight α ; i. e., the inclination of the chord of the surface to the line of translation.

Assuming α constant, however, we may

compare the lift of any particular arched surface with a plane surface of the same projected plan and angle of flight.

To illustrate, in the case of the Wright aeroplane, let us assume

$$P = 1,000 \text{ lb.} = \text{total weight} = W,$$

$$A = 500 \text{ sq. ft.,}$$

$$V = 40 \text{ miles per hour} = 60 \text{ ft. per second,}$$

$$\alpha = 7 \text{ deg. approximately.}$$

Whence

$$\begin{aligned} k\sigma &= P/2AV^2 \sin \alpha = 1,000/(2 \times 500 \times 60^2 \times \frac{1}{2}) \\ &= 0.0022 \text{ (} V = \text{ft. sec.)} \\ &= 0.005 \text{ (} V = \text{mi. hr.)}. \end{aligned}$$

Comparing this value of $k\sigma$ with Langley's value 0.004 for a plane surface V being in miles per hour, we see that the lift for the arched surface is 25 per cent. greater than for a plane surface of the same projected plan. That is to say, this arched surface is dynamically equivalent to a plane surface of 25 per cent. greater area than the projected plan. Such a plane surface may be defined as the "equivalent plane."

Resistance and Propulsion.—The resistance of the air to the motion of an aeroplane is composed of two parts: (a) the resistance due to the framing and load, (b) the necessary resistance of the sustaining surfaces, that is, the drift, or horizontal component of pressure; and the unavoidable skin-friction. Disregarding the frame, and considering the aeroplane as a simple plane surface, we may express the resistance by the equation

$$R = W \tan \alpha + 2fA,$$

in which R is the total resistance, W the gross weight sustained, α the angle of flight, f the friction per square unit of area of the plane, A the area of the plane. The first term of the second member gives the drift, the second term the skin-friction. The power required to propel the aeroplane is

$$H = RV,$$

in which H is the power, V the velocity.

Now W varies as the second power of the velocity, as shown by the first equation, and f varies as the power 1.85, as will be shown later. Hence we conclude that the total resistance R of the air to the aeroplane varies approximately as the square of its speed, and the propulsive power practically as the cube of speed.

Most Advantageous Speed and Angle of Flight.—Again, regarding W and A as constant, we may, by the first equation, compute a for various values of V , and find f for those velocities from the skin-friction table to be given presently. Thus a , R and H may be found for various velocities of flight, and their magnitudes compared.

The question of stability is a serious one in aviation, especially as increased wind velocities are encountered. In machines of the aeroplane type there must be some means provided to secure fore and aft stability and also lateral stability.

A large number of plans have been proposed for the accomplishment of these ends, some based upon the skill of the aviator, others operated automatically, and still others employing a combination of both. At the present time no aeroplane has yet been publicly exhibited which is provided with automatic control. There is little difference of opinion as to the desirability of some form of automatic control.

The Wright aeroplane does not attempt to accomplish this, but depends entirely upon the skill of the aviator to secure both lateral and longitudinal equilibrium, but it is understood that a device for this purpose is one of the next to be brought forward by them. Much of the success of the Wright brothers has been due to their logical procedure in the development of the aeroplane, taking the essentials, step by step, rather than attempting everything at once, as is so often the practise with inexperienced inventors.

The aviator's task is much more difficult than that of the chauffeur. With the chauffeur, while it is true that he requires his constant attention to guide his machine, yet he is traveling on a roadway where he can have due warning, through sight, of the turns and irregularities of the course.

The fundamental difference between operating the aeroplane and the automobile is that the former is traveling along an aerial highway which has manifold humps and ridges, eddies and gusts, and since the air is invisible he can not see these irregularities and inequalities of his path, and consequently can not provide for them until he has actually encountered them. He must feel the road since he can not see it.

Some form of automatic control whereby the machine itself promptly corrects for the inequalities of its path is evidently very desirable. As stated above, a large number of plans for doing this have been proposed, many of them based on gyrostatic action, movable side planes, revolving surfaces, warped surfaces, etc. A solution of this problem may be considered as one of the next important steps forward in the development of the aeroplane.

III. HYDROMECHANIC RELATIONS

At the present moment so many minds are engaged upon the general problem of aerial navigation that any method by which a broad forecast of the subject can be made is particularly desirable. Each branch of the subject has its advocates, each believing implicitly in the superiority of his method. On the one hand, the adherents of the dirigible balloon have little confidence in the future of the aeroplane, while another class have no energy to devote to the dirigible balloon, and still others prefer to work on the pure helicopter principle. As a matter of fact, each of these types is probably of permanent importance, and each particularly adapted to certain needs.

Fortunately for the development of each type, the experiments made with one class are of value to the other classes, and these in turn bear close analogy to the types of boats used in marine navigation. The dynamical properties of water and air are very much alike, and the equations of motion are similar for the two fluids, so that the data obtained from experiments in water, which are very extensive, may, with slight modification, be applied to computations for aerial navigation.

Helmholtz's Theorem.—Von Helmholtz, the master physicist of Germany, who illuminated everything he touched, has fortunately considered this subject, in a paper written in 1873. The title of his paper is "On a Theorem Relative to Movements that are Geometrically Similar in Fluid Bodies, together with an Application to the Problem of Steering Balloons."

In this paper Helmholtz affirms that, although the differential equations of hydro-mechanics may be an exact expression of the laws controlling the motions of fluids, still it is only for relatively few and simple experimental cases that we can obtain integrals appropriate to the given conditions, particularly if the cases involve viscosity and surfaces of discontinuity.

Hence, in dealing practically with the motion of fluids, we must depend upon experiment almost entirely, often being able to predict very little from theory, and that usually with uncertainty. Without integrating, however, he applies the hydrodynamic equations to transfer the observations made on any one fluid with given models and speeds, over to a geometrically similar mass of another fluid involving other speeds, and models of different magnitudes. By this means he is able to compute the size, velocity, resistance, power, etc., of aerial craft from given, or observed, values for marine craft.

He also deduces laws that must inevitably

place a limit upon the possible size and velocity of aerial craft without, however, indicating what that limit may be with artificial power. Applying this mode of reasoning to large birds, he concludes by saying that, "It therefore appears probable that in the model of the great vulture, nature has already reached the limit that can be attained with the muscles as working organs, and under the most favorable conditions of subsistence, for the magnitude of a creature that shall raise itself by its wings and remain a long time in the air."

In comparing the behavior of models in water and air, he takes account of the density and viscosity of the media, as these were well known at the date of his writing, 1873; but he could not take account of the sliding, or skin-friction, because in his day neither the magnitude of such friction for air, nor the law of its variation with velocity had been determined.

Even as late as Langley's experiments, skin-friction in air was regarded as a negligible quantity, but, due to the work of Dr. Zahm, who was the first to make any really extensive and reliable experiments on skin-friction in air, we now can estimate the magnitude of this quantity. As a result of his research he has given in his paper on atmospheric friction the following equation:

$$f = 0.00000778 \, l^{-0.07} v^{1.88} \dots (v = \text{ft. sec.}),$$

$$f = 0.0000158 \, l^{-0.07} v^{1.88} \dots (v = \text{mi. hr.}),$$

in which f is the average skin-friction per square foot, and l the length of surface.

Relative Dynamic and Buoyant Support.—Peter Cooper-Hewitt has given careful study to the relative behavior of ships in air and in water. He has made a special study of hydroplanes, and has prepared graphic representations of his results which furnish a valuable forecast of the problem of flight.

Without knowing of Helmholtz's the-

orem, Cooper-Hewitt has independently computed curves for ships and hydroplanes from actual data in water, and has employed these curves to solve analogous problems in air, using the relative densities of the two media, approximately 800 to 1, in order to determine the relative values of support by dynamic reaction and by displacement for various weights and speeds.

An analysis of these curves leads to conclusions of importance, some of which are as follows:

The power consumed in propelling a displacement vessel at any constant speed, supported by air or water, is considered as being two thirds consumed by skin-resistance, or surface resistance, and one third consumed by head resistance. Such a vessel will be about ten diameters in length, or should be of such shape that the sum of the power consumed in surface friction and in head resistance will be a minimum (torpedo shape).

The power required to overcome friction due to forward movement will be about one eighth as much for a vessel in air as for a vessel of the same weight in water.

Leaving other things out of consideration, higher speeds can be obtained in craft of small tonnage by the dynamic reaction type than by the displacement type, for large tonnages the advantages of the displacement of type are manifest.

A dirigible balloon carrying the same weight, other things being equal, may be made to travel about twice as fast as a boat for the same power; or be made to travel at the same speed with the expenditure of about one eighth of the power.

As there are practically always currents in the air reaching, at times, a velocity of many miles per hour, a dirigible balloon should be constructed with sufficient power to be able to travel at a speed of about 50 miles per hour, in order that it may be available under practical conditions of

weather. In other words, it should have substantially as much power as would drive a boat, carrying the same weight, 25 miles an hour, or should have the same ratio of power to size as the *Lusitania*.

Motors.—It is the general opinion that any one of several types of internal combustion motors at present available is suitable for use with dirigible balloons. With this type, lightness need not be obtained at the sacrifice of efficiency. In the aeroplane, however, lightness per output is a prime consideration, and certainty and reliability of action is demanded, since if by chance the motor stops, the machine must immediately glide to the earth. A technical discussion of motors would of itself require an extended paper, and may well form the subject of a special communication.

Propellers.—The fundamental principles of propellers are the same for air as for water. In both elements, the thrust is directly proportional to the mass of fluid set in motion per second. A great variety of types of propellers have been devised, but, thus far only the screw-propeller has proved to be of practical value in air. The theory of the screw-propeller in air is substantially the same as for the deeply submerged screw-propeller in water, and therefore does not seem to call for treatment here. There is much need at present for accurate aerodynamic data on the behavior of screw-propellers in air, and it is hoped that engineers will soon secure such data, and present them in practical form for the use of those interested in airship design.

Limitations.—Euclid's familiar "square-cube" theorem connecting the volumes and surfaces of similar figures, as is well known, operates in favor of increased size of dirigibles, and limits the possible size of heavier-than-air machines in single units and with concentrated load.

It appears, however, that both funda-

mental forms of aerial craft will likely be developed, and that the lighter-than-air type will be the burden-bearing machine of the future, whereas the heavier-than-air type will be limited to comparatively low tonnage, operating at relatively high velocity. The helicopter type of machine may be considered as the limit of the aeroplane, when by constantly increasing the speed the area of the supporting surfaces is continuously reduced until it practically disappears. We may then picture a racing aeroplane propelled by great power, supported largely by the pressure against its body, and with its wings reduced to mere fins which serve to guide and steady its motion. In other words, starting with the aeroplane type, we have the dirigible balloon on the one hand as the tonnage increases, and the helicopter type on the other extreme as the speed increases. Apparently, therefore, no one of these forms will be exclusively used, but each will have its place for the particular work required.

GEORGE O. SQUIER

MOSQUITO EXTERMINATION WORK IN NEW JERSEY

PROFESSOR JOHN B. SMITH, in his report to the governor on the work carried on under the law of 1906, shows that up to the end of the summer of 1908 there had been drained 20,292 acres of salt marsh extending from the Hackensack River to the mouth of Toms River on Barnegat Bay. To accomplish this, required 2,723,974 feet of ditching, put in at an actual cost of \$44,058, some \$12,000 being expended for administration, surveys and other work necessary to control the actual carrying out of the contracts.

During the same period of two years municipalities throughout the state have joined in the mosquito crusade, and have expended considerable sums of money for local work in eliminating breeding areas. The work is all in the direction of permanent improvement and of destroying the breeding localities. Oiling and temporary work is done only when it

is necessary to destroy a brood of wigglers that might otherwise hatch before permanent work can be done.

The results have been very gratifying and the migrating marsh mosquitoes were almost entirely absent during most of the summer from the larger cities where drainage work had been done in 1907 or earlier. It developed in the course of the work that the eggs of these salt marsh species retain their vitality for a very long period and that for at least three years after a marsh is drained, there may be ever lessening broods of larvæ found whenever it becomes water-covered by freshet tides or heavy rains. This was interestingly shown by examinations of marsh mud, from areas drained for different periods, and counting the eggs and egg shells on the samples. It is, therefore, a rather slow process to completely clean up such areas, because a few specimens developing under favorable circumstances will provide a small stock of eggs that require three years or more to work out altogether. In the areas drained in 1904, however, practically no eggs were found except in the deepest depressions, and even in these they were very few in number and much scattered.

The season of 1908 was remarkable for the excessive rainfall in early spring, which provided breeding areas for the early brood, far beyond usual conditions, and these afterward concentrated in cisterns, water-barrels, sewer catch-basins and similar localities so that cities were much troubled by them in the entire region where these excessive spring rains prevailed.

If the legislature now in session provides sufficient means, it is expected that the drainage work can be carried to Great Bay during the season of 1909, and in the cities the local committees are already providing against a duplication of last season's experience with the house mosquito.

THE AMERICAN MUSEUM OF NATURAL HISTORY

THE annual meeting of the trustees of the American Museum of Natural History was held on Monday, February 8. The following officers were elected: Henry Fairfield Osborn,

president; J. Pierpont Morgan, first vice-president; Cleveland H. Dodge, second vice-president. The following is an abstract of the president's annual report:

In point of growth the past year has been the most notable in the history of the institution. Partly aided by the Jesup bequest, the total expenditures were \$275,419, or \$25,000 more than the previous year. Of this the city contributed \$159,930.62 and the museum \$115,488.38. In the past eight years the museum has expended directly \$932,008 on its explorations and collections. The estimated total value of the collections secured during this period by exploration, by purchase, and by gift to the museum is over \$2,000,000. For every dollar which has been expended by the city more than a dollar has been added to the enlargement of the collections.

The present endowment fund, including the bequest of the late President Jesup, is \$2,048,156.61. To keep pace with the very rapid growth of the city and the demands it is making for public scientific education, an endowment fund of \$5,000,000 is needed. In every part of the world the advance of agriculture and commerce and the spread of fire arms is rendering more scarce the objects of natural history of all kinds, including the works of the primitive races of men. It is deemed vitally important to push the explorations of the museum in all parts of the world while it is still possible to secure these fast vanishing works of nature and of primitive man. During the year 1908 and at the present time the museum's explorations extend to the Mackenzie River and the shores of the Beaufort Sea, to Alaska, Vancouver, Alberta and Saskatchewan, the west coast of Hudson Bay and western Labrador; in the United States parties have been spread in Wyoming, Montana, Idaho, North Dakota, Nebraska, Colorado and Florida, also in Central America, and in the south to Nicaragua, the West Indies and Bahama Islands; in Asia special agents are working in Kashmir, China and Corea; among the islands of the Pacific the museum is working in the Philippines, the Solomon Islands, in Tahiti, New Zealand, the South Shetland Islands and in Kerguelan Island.

Popular education has been given a stronger impulse than ever before. The museum was open free to the public every day of the year and on 179 evenings. The gross attendance last year was 1,043,582, in large part due to the exceptional interest in the International Tuberculosis Exhibition. The attendance at public afternoon and evening lectures reached a total of 82,718. The number of children visiting the museum in lecture classes was 10,425. The number of children who were especially guided through the Tuberculosis Exhibition and who listened to lectures on simple means of prevention of this disease was 41,627. These children came from all the high schools of Greater New York and from many distant towns and cities. In the schools of the city 575,801 children were reached by the system of circulating museums.

During the coming year the principal new exhibitions which will be developed are especially the Children's Museum, the Museum for the Blind, the Philippine Exhibition and the Congo Exhibition presented by King Leopold of Belgium. This last is the most complete collection outside of that which is to be seen in the Congo Museum near Brussels. Growing out of the Tuberculosis Exhibition immediate steps will be taken to make a special exhibition of the life and habits of the smaller organisms in relation to health and disease.

During the past year the scientific staff of the museum has been strengthened by the addition of Professor Bashford Dean, a traveler and ichthyologist of international reputation, who has been placed in charge of the fishes and reptiles. Professor Henry E. Crampton, also of Columbia University, has been appointed head curator of the department of invertebrate zoology to succeed Professor William Morton Wheeler, who has resigned to accept a professorship in Harvard University. Dr. Frank E. Lutz has been called from the Carnegie Institution of Experimental Evolution to take special charge of the exhibition of microorganisms in relation to public health. Dr. Alexander Petrunkevitch has been appointed honorary curator of arachnida, and Aaron L. Treadwell, of Vassar College, has been appointed honorary curator of annulates.

THE EIGHTH INTERNATIONAL ZOOLOGICAL CONGRESS

A LETTER recently received from Professor von Graff contains some information concerning the eighth International Zoological Congress, which will be held in Graz, Austria, in August, 1910, under his presidency. The exact dates are not yet determined, but the meetings will follow those of the Anatomical Congress to be held the same month in Brussels.

Graz is a city of about 130,000 inhabitants, beautifully situated at an elevation of 1,500 feet in the foot-hills of the Styrian Alps, and will be best approached by those coming from the west by the picturesque mountain road from Innsbruck. It has narrow, crooked streets in the older parts of the city and fine, new University buildings for the third educational institution of the empire. The city is overlooked by a fine park and it is proposed to have the evening meals served in one of the beautiful resorts in the neighborhood.

The present plans are to have the sessions occupy the week, from Monday to Friday, the general sessions coming in the morning, those of the sections in the afternoon. The number and character of the sections can not be stated at present, as they depend on the number of papers presented. On Saturday the plan is to make an excursion to Leoben, a beautifully situated village in the Styrian Erzberg, spending the night there.

On Sunday the train is taken over the new alpine railroad to Trieste. Monday forenoon is given to a visit to the Zoological Station at Trieste, founded by the late Professor Olaus and famous for the character and amount of its work. Then a visit is made to the picturesque villa of Miramar, associated with the name of the unfortunate Maximilian, of Mexico. Rovigno with its zoological station is reached in the afternoon, and in the evening of Monday the steamer is taken for the four days trip down the beautiful and comparatively little known Dalmatian coast, with its mountainous background, its picturesque costumes and its magnificent remains of the later Roman empire. Stops will probably be made at Sebenico, Spalato, Ragusa and Cat-

taro, and from the latter place a ride of only a few hours takes one over the border and into the strange city of Cetinge, in Herzegovina. Friday brings the party back to Trieste, but arrangements may possibly be made, allowing those who wish, to stop over longer in Dalmatia. Those who return with the party will reach Vienna on Saturday, and the Congress will finally disband on Sunday.

Those who are interested should write to Professor L. von Graff, Graz, Stiermark, Austria, asking that the circulars, when issued, be sent them. Already several Americans have signified their intention to attend.

PROPOSED LINCOLN SCHOOLS OF SCIENCE

THE Minnesota Academy of Science has passed the following resolution:

WHEREAS: This meeting of the Minnesota Academy of Science takes place near the date of the one hundredth anniversary of the birth of Abraham Lincoln, and

WHEREAS: It is suitable and incumbent on the American people, in gratitude for the great service and sacrifice rendered by him to the fundamental elements of American civilization, to perpetuate his name and to honor it by inscribing it in conspicuous places where the youth may frequently be reminded of the excellence of his character, and

WHEREAS: The American Congress has by a commission appointed for this purpose, after long and extended consideration, recommended the construction of a great thoroughfare from Washington City to the battlefield of Gettysburg, and

WHEREAS: Still there seems to be room and opportunity to commemorate the name of Lincoln in a line of science in which he was a prominent actor, and

WHEREAS: It was by his signing and approving of the act of Congress of 1861 establishing the state schools known as Colleges of Agriculture and Mechanic Arts, to the maintenance of which this nation is committed, and which have since been called "National Schools of Science," of the United States, that the science of agriculture and mechanics have been benefited and firmly established in the educational curricula of the country, therefore,

Resolved, That it is the opinion of the members of the Minnesota Academy of Science that the name of Lincoln ought to be applied by Congress to these schools, and that all the literature and all the researches from such schools that may hereafter be published ought to be labeled and

everywhere known as products of the "Lincoln Schools of Science."

It is the opinion of this academy that by so designating these schools, while an immaterial and uncostly honor would be conferred on the greatest American citizen, such honor would be likely to be more influential and more durable in the perpetuation of his memory than the expenditure of large sums of money in material monuments of any kind.

FIRST AWARD OF THE LANGLEY MEDAL

THE first award of the gold medal recently established by the Smithsonian Institution in memory of the late Secretary Samuel Pierpont Langley and his contributions to the science of aerodromics is made to Wilbur and Orville Wright. The board of regents of the institution has adopted the following resolution:

Resolved, That the Langley medal be awarded to Wilbur and Orville Wright for advancing the science of aerodromics in its application to aviation, by their successful investigations and demonstrations of the practicability of mechanical flight by man."

Following the establishment of the Langley medal, Secretary Walcott appointed the following-named gentlemen of known competence in the subject of aerodromics as a committee on award, announcement of which is hereby made: Mr. Octave Chanute, of Chicago, Chairman; Dr. Alexander Graham Bell; Major George O. Squier, U. S. A.; Mr. John A. Brashear, of Allegheny, Pa., and Mr. James Means, formerly editor of *The Aeronautical Annual*, Boston. The Langley Medal was founded "to be awarded for specially meritorious investigations in connection with the science of aerodromics and its application to aviation." The original design to be used for this medal was made by Mon. J. C. Chaplain, of Paris, a member of the French Academy. The medal bears on its obverse a female figure, seated on the globe, carrying a torch in her left hand and in her right a scroll emblematic of knowledge and the words "Per Orbem." The reverse is adapted from the seal of the institution as designed by Augustus St. Gaudens, the special inscription being inserted in the cen-

ter instead of the map of the world. It is about three inches in diameter.

SCIENTIFIC NOTES AND NEWS

THE Astronomical Society of the Pacific has awarded its Bruce gold medal for the year 1909 to Dr. G. W. Hill for distinguished services to astronomy.

THE eminent mathematician, M. Henri Poincaré, was officially received on January 28 into the French Academy, taking the seat vacant by the death of the poet Sully Prudhomme. M. Frédéric Masson, the historian of Napoleon, made the address of welcome.

LORD RAYLEIGH, who left England with Lady Rayleigh for a six months' tour around the world, has been seriously ill in South Africa, but is now better. He has given up his plan of going to Australia, and will probably finish the winter in Egypt.

THE celebration of Haeckel's seventy-fifth birthday was held in Jena on February 16. As a gift from the American Museum of Natural History to the Phyletic Museum Professor Osborn has sent a series of the large reproductions of Charles R. Knight's restorations of the extinct vertebrates of North America.

DR. S. WEIR MITCHELL celebrated his eightieth birthday on February 15.

PROFESSOR RAMON Y CAJAL, the anatomist, has been created a senator of Spain.

M. LOUIS MANGIN has been elected a member of the Paris Academy of Sciences, in the section of botany, to succeed M. Van Tieghem, who has been elected permanent secretary.

PROFESSOR WILLIAM Z. RIPLEY, of Harvard University, has been elected an honorary fellow of the Royal Anthropological Institute of Great Britain and Ireland, in recognition of his researches in the field of European and American demography.

PORTRAITS of Professor George J. Brush and of Professor William H. Brewer have been hung in the recently fitted-up faculty room of the Sheffield Scientific School, Yale University. Professor Brush and Professor

Brewer both graduated from the school in the class of 1852.

A NUMBER of physicians who have been operated on by Dr. John B. Deaver, of Philadelphia, gave a dinner in his honor at the University Club on February 14. More than 150 physicians are included in this category. A loving cup was presented to Dr. Deaver.

THE election of Professor S. Kitasato, director of the Infectious Diseases Institute, at Tokyo, to the honorary fellowship of the Royal Society has been made the occasion of a dinner given in his honor by a number of his pupils and friends. Congratulatory addresses were delivered by Professor Kitajima and Dr. T. Takaki, director of the Formosan Medical Institute.

THE title of honorary keeper of the Ashmolean Museum, Oxford, has been conferred upon Dr. Arthur Evans "in consideration of his eminent services to the university as keeper of the Ashmolean Museum, extending over twenty-five years." The thanks of the university were also given to Dr. Evans for his recent gift to the museum.

DR. KARL J. ORCHSLIN, of Leipzig, for the past year associated with Professor Michael, of Tufts College, began his new work in the Division of Chemistry, Bureau of Science, Manila, P. I., on January 1.

MR. CHARLES S. BANKS has resumed his duties as entomologist in the Bureau of Science, Manila, P. I., after five months spent in America and Europe in the identification of Philippine material. He worked largely on Philippine Culicidæ, Hemiptera and Orthoptera in the British Museum, and with Dr. Bouvier, in Paris, on Mallophaga, and Dr. Leonardi, in Portici, on Coccidæ and Termitidæ.

PROFESSOR J. B. WOODWORTH, of the geological department, of Harvard University, has returned to Cambridge from his extended trip in South America. He left Cambridge last June and has spent the intervening time in scientific investigation in Brazil and on the western coast of the continent. The trip was made possible by the Shaler Memorial Fund

and is the first of a series of similar expeditions to be made under the same provision.

MR. GEORGE H. SHULL, of the Cold Spring Harbor Station for Experimental Evolution, has returned from a three-months' trip to Europe undertaken for the purpose of studying scientific and economic plant breeding. He has now gone to California to resume his work on Mr. Burbank's methods and results.

MR. and MRS. C. WILLIAM BEEBE sailed for Georgetown, British Guiana, on February 15, on the Royal Dutch mail steamer *Copename*. A month or more will be spent in the interior for the purpose of studying the more generalized types of birds inhabiting this country. Mr. Lee S. Crandall will accompany Mr. Beebe as assistant, and the attempt will be made to bring back alive for the New York Zoological Park some of the more interesting birds and other animals.

MR. ELLSWORTH HUNTINGTON, of the geological department of Yale University, sailed on February 10 on the *Majestic* for Southampton. He is going to Jerusalem by the way of Constantinople, taking with him Mr. C. F. Graham, a Yale senior, as assistant. They will study the former shorelines around the Dead Sea. Their plan is to use a folding boat and visit various points on its shores. The special problem to be solved by this expedition is as to whether any of the shorelines record expansions of this sea within historic times. After leaving the Dead Sea some two months will be spent in the study of the geography of Palestine and the Syrian Desert, with special reference to changes of climate and the effect which the geographic environment has had upon the people and their history. The third objective point will be in the lake region of Asia Minor, where some three months will be spent in the study of the same problems of shorelines, climate and man. This expedition is made under the auspices of Yale University, which defrays a portion of the expenses.

PROFESSOR JULIUS STIEGLITZ, of the University of Chicago, will deliver shortly at the University of California a series of eight or ten lectures, on some aspect of chemistry. This will be the first series of lectures on the

Hitchcock foundation, provided for by the bequest of C. M. Hitchcock in 1885.

SIR JAGADIS CHUNDER BOSE, M.A., Sc.D., professor of physics and biology at the Presidency College, Calcutta, India, recently lectured at the University of Illinois on the subjects of the polarization of electric waves, the mechanical responses of plants, and the electric responses of plants.

PROFESSOR WILLIAM T. SEDGWICK, of the Massachusetts Institute of Technology, will give a series of lectures at the University of Illinois, from April 19 to 24, under the general head of "Science in the Service of Public Health."

A SERIES of public lectures is to be given at Columbia University on March 8, 15 and 22 at 5:10 P.M. by Alexander S. Chessin, professor of mathematics in Washington University, on the gyrostatis. The first lecture will be devoted to a brief history of the gyrostatis showing its development from a mere toy into a scientific instrument and a mechanism of great value. The second lecture will be on the influence of the world's rotation on the motion of gyrostats, Foucault's top and the applications of the gyrostatis to astronomy and to surveying. The third lecture will be upon the gyrostatis in modern industries, and will be devoted to the devices for torpedoes, the steadying of ships at sea, the Schlick marine gyrostatis, the mono-rail car, and the experiments of the German navy, all fully illustrated.

At the last meeting of the Middletown Scientific Association, held on February 9, Professor William North Rice spoke on the life of Darwin.

IN accordance with the plan which we have already announced, a heroic bronze bust of Darwin, by the sculptor Mr. William Couper, was presented by the New York Academy of Sciences to the American Museum of Natural History on February 12. The address of presentation was made by Mr. C. F. Cox, president of the academy, and the bust was accepted on behalf of the trustees of the museum by Dr. H. F. Osborn, president. Addresses were then made on "Darwin and Geology," by Professor J. J. Stevenson; "Darwin and

Botany," by Dr. N. L. Britton, and "Darwin and Zoology," by Dr. Hermon C. Bumpus. In connection with the celebration a special exhibition has been installed in the museum, consisting of Darwiniana and series of specimens and groups of specimens bearing upon the Darwinian theory of evolution through natural selection. The exhibition will continue for one month.

PROFESSOR AUGUST WEISMANN finds himself unable, in consequence of his advanced age, to accept the invitation of the University of Cambridge to attend the Darwin Centenary celebrations and to deliver an address.

DR. GEORGE E. HALE, of the Solar Observatory on Mount Wilson, has been appointed a delegate to represent the National Academy of Sciences at the Darwin Celebration at Cambridge.

THE Cambridge University Press will present to each invited guest at the approaching Darwin centenary celebration a copy of the first draft of "The Origin of Species," which is being prepared for press and edited by Mr. Francis Darwin. This is the draft of which Mr. Darwin speaks in his autobiography: "In June, 1843, I first allowed myself the satisfaction of writing a very brief abstract of my theory in pencil in 35 pages."

MR. WALTER MORRISON ALLEN, known as a designer of telescopes, died in Cleveland on February 8, at the age of forty-two years.

MR. WILFRED HUDDLESTON, F.R.S., the eminent British geologist, died at his home at Dorset on January 29, in his eighty-first year. The death is also announced of M. A. Legoux, who for many years occupied the chair of mechanics at Toulouse.

THE general secretaries of the British Association have issued a preliminary circular in regard to the meeting at Winnipeg beginning on August 25. No reduction in rates is made by the steamship companies, but special accommodation will be reserved on the Canadian Pacific steamship *Empress of Ireland*, sailing from Liverpool to Montreal on August 18. It is expected that a single fare will be granted on the Canadian railways for the return trip from Montreal to Winnipeg and from Winni-

peg to Victoria. The official party will leave Winnipeg at midnight on September 2 for the trip to the Pacific coast, and will return to Winnipeg on September 13.

THE fiftieth anniversary of the founding of the Paris Society of Anthropology will be celebrated July 7-9, 1909. Anthropological societies and institutions are invited to send delegates. The program includes a discourse by the minister of public instruction and fine arts, an address by the president of the society, a report by the general secretary on the scientific activities of the society since its foundation, and messages from delegates who are to be the guests of the society at a luncheon and a dinner.

THE Royal Institution, London, has received from a lady who wishes to remain anonymous a gift of £10,000.

THE trustees of the Elizabeth Thompson Science Fund are prepared to receive applications for appropriations in aid of scientific work. All applications should reach, before March 15, 1909, the secretary of the board, Dr. C. S. Minot, Harvard Medical School, Boston, Mass.

ACCORDING to the Berlin correspondent of the London *Times* the latest available details of the new German airship Zeppelin II., which will be launched in March, state that the total length of the vessel is 446 feet, the diameter 42 feet 8 inches, and the cubic contents about 530,000 feet of hydrogen. There are 17 ballonets, of which 16 are of india-rubber-treated cotton, and the seventeenth is of gold-beaters' skin, and is supplied by a well-known firm of English aeronauts. The two Daimler motors weigh 798.8 pounds, and produce together about 200 horse power. The two aluminium cars form cabins for the captain, hammocks being provided for the men. The cars are furnished underneath with soft fenders in order to lessen the shock of landing on the hard ground. An immense shed is being built to accommodate Zeppelin II. as soon as it is launched.

THE production of petroleum in the United States in 1908, according to a preliminary

estimate made by David T. Day, of the United States Geological Survey, amounted to between 175 and 180 million barrels, an increase between 5 and 9 per cent. as compared with the production of 166 million barrels in 1907. The total value of the product showed an even greater proportionate gain, for the price of oil increased in California and remained steady in other fields except the Gulf. The increases are attributed to steady growth in Illinois and California, though neither field showed phenomenal development.

MR. D. O. MILLS has given to the department of mammalogy of the American Museum of Natural History eight specimens of the fur seal, to be utilized in the preparation of a group illustrating a seal rookery. The specimens were collected at the Pribilof Islands, Alaska, expressly for the museum, by order of Mr. Mills, who had special permission from the Department of Commerce and Labor for their capture. The series consists of male seals two, three, five and seven years old, female seals three and four years old and two pups six weeks old.

BARON DE LENVAL, on the occasion of the Third International Otological Congress, founded a prize of 3,000 francs to be awarded to such person as should invent and produce a small portable instrument materially assisting the hearing of the deaf. As no such instrument has yet been forthcoming to the satisfaction of the international jury appointed to adjudicate upon the matter, the accumulated interest of four years, amounting to about 400 francs, will be awarded as a prize for the best work that has been published during the last four years in the departments of the anatomy, physiology, or pathology of the organ of hearing. Competing works should be sent to the president of the jury, Professor Dr. A. Politzer, I. Gonzagasse 19, Vienna, before the end of February.

UNIVERSITY AND EDUCATIONAL NEWS

THE two hundred thousand dollars required to secure the gift of \$600,000 from Mr. John D. Rockefeller for the Harper memorial library at the University of Chicago has now

been secured. A building will be erected, but part of the money has been reserved for an endowment.

PRESIDENT CHARLES F. THWING, of Western Reserve University, announces the completion of a \$500,000 fund for additional endowment of Adelbert College and the college for women. Of this amount \$125,000 was offered by the General Education Board, on the condition that \$375,000 be raised by the university.

HAMLIN UNIVERSITY, St. Paul, Minn., has been offered \$75,000 by the General Education Board of New York on the condition that it will raise three times the amount, making a total of \$300,000, a large portion of which is to be added to the permanent endowment.

THE department of engineering of the University of Michigan has received a gift of the library of the late George Y. Wisner and a rotary engine of the value of \$7,000 from Mr. J. D. R. Lampson.

AMERICANS who have received honorary degrees at Oxford have made through President Butler, of Columbia University, a gift of \$1,200 for the endowment fund.

LORD WINTERSTOKE has offered to give an additional £15,000 towards the proposed Bristol University. This will make a total contribution from him of £35,000.

WE are informed that the statement quoted here from the daily papers to the effect that the office of chancellor would be established at the University of Michigan for President Angell to hold after his resignation is incorrect.

THE daily papers state that the presidency of Dartmouth College has been offered to Mr. S. W. McCall, member of congress from Massachusetts since 1893 and a graduate of Dartmouth College in the class of 1874. Statements in regard to college presidencies printed in the daily papers seem, however, to have a large probable error.

DR. FLETCHER B. DRESSLAR, associate professor of education at the University of California, has become head of the department of philosophy and education in the University of Alabama.

DISCUSSION AND CORRESPONDENCE

HARVARD UNIVERSITY AND THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY

TO THE EDITOR OF SCIENCE: I note in SCIENCE of January 29 a quotation from a Boston newspaper in regard to "Harvard University and the Massachusetts Institute of Technology"; and it seems desirable that certain erroneous impressions conveyed therein should be corrected.

The important misconception in the article in question is implied in the statement: "It seems probable that the taking from the institute by Harvard of two of its leading professors will bring up again the question of a consolidation or of an alliance between these two educational institutions." This is not only not probable; it is entirely unthinkable, to those acquainted with the true situation. The opposition of the faculty and alumni of the institute to this plan is founded on good and substantial reasons, which are too generally understood and respected to be questioned again.

The Technology faculty and alumni did not oppose the proposed alliance from mere pride in the achievements of the institute, or from any narrow fear that it would lose its individual reputation. They simply recognized that Harvard and Technology represent different and incompatible educational ideals. Harvard's ideal is that of graduate scientific schools following a college course based on the elective system. This, so far as engineering goes, is an interesting and promising experiment and one to which Technology can cheerfully contribute two of her honored sons. Technology herself, however, stands for a different ideal, for a combination, from the beginning, of a broad scientific training with the elements of liberal culture, in a four years' course, laid along the lines of a carefully balanced group system of studies. This ideal has not been fully realized; few ideals ever are; yet in the flux of doubt and questioning which seems to have engulfed the world of higher education, the record of what the institute has actually accomplished stands out as one of the

clear and positive achievements of the last half century.

I almost apologize for calling attention to another sentence in the quotation: "The institute, on the other hand, is handicapped by an improper location and insufficient funds to compete successfully against Harvard."

The readers of *SCIENCE* ought to be assured that while Technology needs, and would gladly receive, gifts for its growing work, it has so far been able to make both ends meet without serious difficulty. The new president, Professor MacLaurin, experienced in education on three continents, comes to the institute with complete enthusiasm for its special ideals. A body of eight thousand alumni and past students stand ready for loyal service. The institute is now contemplating a move from its present location, which it will soon outgrow, to a new and ample one where a group of buildings worthy of its dignity will be erected. "The Old Technology, with its old traditions and its old ideals, new built on a new site," as acting President Noyes recently phrased it, will not "compete against Harvard"; but it will welcome the McKay school of applied science as a worthy ally in the great war against ignorance that we are all waging together.

C.-E. A. WINSLOW

THE RIGHT AND THE WRONG IN POPULAR SCIENCE BOOKS

To put in simple and elegant language descriptions and explanations of natural phenomena is to offer every one that knowledge and understanding that broadens our sympathies; that increases our interest in the world about us; that makes us more contented and more useful human beings. No nobler work than this can any man do—the work that Tyndall, that Sir Robert Ball, that Darwin and many another devoted follower of nature loved so much and did so well. The popular books that men like these produce can never be too numerous, nor can the publisher devote to them more of his beautifying art than they deserve.

Unfortunately, however, there is another class of books with natural phenomena for

their titles; books, of which the one under review is typical, attractively written and prettily illustrated, but filled with false explanations—counterfeit mental coin palmed off on the innocent, to their inestimable harm. Such books do not spread knowledge, nor do they even leave the mental tablets of the uninformed receptively blank, but, on the contrary, scribble all over them an almost ineradicable jumble of errors, which must somehow be got rid of before the unfortunate victims is ready even to begin to learn the truth.

Surely the author of a book treating of a scientific subject must know that he knows what he is talking about, or know that he doesn't know. In the first case, let his explanations be simple, clear, complete. In the second let him have sufficient judgment to leave attempted explanations alone, for they are sure to be wrong, and therefore harmful.

But the fault is not alone with the author. The publisher is expected, and properly so, to guarantee, to the best of his knowledge, the accuracy of the books he offers for sale. And this, it would seem, should impose upon him the duty of submitting all manuscripts of popular nature-books to competent specialists. In this way "Water Wonders Every Child Should Know,"¹ like many another of its kind, might easily have been made the excellent book that at first glance it appears to be, instead of the thing of blunders it actually is.

This little book is beautifully got up, attractively written and filled with many of Mr. Bentley's choicest snow and frost photographs, but as it now stands it can be recommended to those only who already have a knowledge, sufficient to protect them from its errors, of the subjects, dew, frost, snow, ice and rain, of which it treats; and to them simply for its beautiful pictures. But these latter are so numerous and so beautiful that it is to be hoped that there will soon be a new and properly revised edition, one that can be recommended for the accuracy of its explanations as well as for the beauty of its illustrations.

W. J. HUMPHREYS

¹ Jean M. Thompson, "Water Wonders Every Child Should Know," Doubleday, Page & Co., 1907.

QUOTATIONS

THE UNIVERSITY PRESIDENT AND THE UNIVERSITY PROFESSOR

IN Professor A. Lawrence Lowell's first formal address as president-elect of Harvard University, printed in the *Harvard Bulletin*, he says:

It is commonly thought that President Eliot has ruled Harvard and the faculty with a heavy hand. It is not so. When I went to Cambridge one of my colleagues said to me: "If you fail to give satisfaction you will go; but so long as you give satisfaction you may teach as you please." That has been President Eliot's method of treating his subordinates, the members of the faculty.

Is it to be understood that as president of Harvard University Mr. Lowell proposes to retain his subordinates only so long as they give him satisfaction?

The president of another great university has recently expressed his opinion of the relation between the university president and the university professor. In his recently printed lectures before the University of Copenhagen, President Butler, of Columbia University, writes:

Almost without exception the men who to-day occupy the most conspicuous positions in the United States have worked their way up, by their own ability, from very humble beginnings. The heads of the great universities were every one of them not long ago humble and poorly compensated teachers.—An 'Umble Professor in *The Nation*.

MAMMALS IN THE CONGRESS

Mr. Macon—"Another question. I notice that it is proposed to preserve mammals. What kind of mammals are there up there? I notice here some mammals that you want to preserve there. What are mammals, and of what use will they be to the government?"

Mr. Gronna—"So far as I know, there are no mammals on the islands. The species of birds we have, I have mentioned. We have also the white pelican——"

Mr. Macon—"Are these mammal birds?"

Mr. Gronna—"We have on those particular islands birds that are found nowhere else in the United States, I will say to the gentleman from Arkansas. We have the white-winged

scoter, that is not found anywhere else in the interior of this country."

Mr. Macon—"But I want to know about the mammals."

Mr. Gronna—"I am not discussing or referring to mammals."

Mr. Macon—"But I want to know about them."

Mr. Gronna—"I am talking about birds."

Mr. Macon—"I have understood they are something like rats, gophers, or something of that kind."

Mr. Humphreys—"Or 'possum."

Mr. Macon—"Oh, no——"

Mr. Gronna—"I will say in reply to the gentleman from Arkansas that if there are any mammals there of any value we will be very much pleased to preserve them."

Mr. Macon—"But what are they good for?"

Mr. Gronna—"I say we have none that I know of."

Mr. Macon—"What are they good for, or what would they be good for if they were there?"

Mr. Gronna—"I will say to the gentleman from Arkansas that my reply to the gentleman was this, that if there are any mammals of any value we would desire to preserve them."

Mr. Macon—"I am trying to get at what they are good for, but it seems that the gentleman can not inform me."

SCIENTIFIC BOOKS

Pulmonary Tuberculosis and Its Complications. By SHERMAN G. BONNEY, M.D., Professor of Medicine, Denver and Gross College of Medicine, Denver. 8vo, pp. 778, with 180 original illustrations, including 20 in colors and 60 X-ray photographs. Philadelphia and London, W. B. Saunders Company. 1908. Cloth, \$7 net; half moreocco, \$8.50 net.

Dr. Bonney has given us a most valuable book, and one replete with interest. It embodies "largely the results of personal experience." Dr. Bonney has for many years enjoyed a large practise, and has had unusual opportunities for clinical study, which have

been put to good use. His observations and conclusions have therefore great value.

While the book is, as he says, designed for the general practitioner, one of the best written and strongest portions is Part VI., section I., in which he deals with Prophylaxis. Under this general head we find discussed Notification and Registration, Education for the Consumptive and the Public, the giving of Material Aid, and Administrative Control. These chapters are well adapted for general reading, and we wish that the educated public, and especially those charged with the making and administration of our laws, could be forced to study them. A single quotation only can be given:

Society, which sometimes encompasses the regular and legitimate practitioner of medicine with embarrassing restrictions, yet permits the unsuspecting invalid to become the non-defensive prey of ignorant and unscrupulous charlatans. While many forms of quackery have been overlooked, and the advertisement and sale of patent medicines containing alcohol and various narcotics have been permitted, the state, by virtue of its failure to enact repressive legislation or to enforce existing laws, has become indirectly responsible for the lack of public health.

At present interest is again turned to the relation between bovine and human tuberculosis. Dr. Bonney's conclusions are in the main sound and practical. While admitting the danger to man from cattle, he says: . . . "among individuals a greater virulence attaches to the bacillus of human origin than to the bovine." This statement is incorrect. If it means that the consumptive man is the chief source of danger to man, we will agree with it, but no one has ever shown that the human bacillus is more virulent for man than the bovine germ, and there is good reason to believe that the contrary is true.

The discussion of staining is meager, and no mention is made of the non-acid-fast forms of the tubercle bacillus, a most important matter pointed out by E. Klebs, Much, Michaelides, Herman and others. What he says against waiting to make a diagnosis until tubercle bacilli are found in the sputum is eminently sound. Much valuable time is lost,

and many lives sacrificed by this wide-spread, but most pernicious, practise.

The methods given for isolation of cultures are incorrect.

The sections of the book which will probably most interest the practitioner are those on diagnosis, symptomatology, complications and treatment. These occupy the major portion of the book, and are illustrated by many excellent and well-chosen cuts.

The classification of cases is not in accordance with the modern trend, and no mention is made of the classification advised by the National Association.

The subject-matter in these sections is very full and contains a vast amount of practical knowledge.

Sixty X-ray photographs are given, most of them excellent. Dr. Bonney properly regards the X-ray as a valuable aid to diagnosis. He considers the "legitimate scope of the subcutaneous tuberculin test to be extremely limited," though he says it is "not only harmless, but has a high diagnostic value" when intelligently employed. While recognizing the care necessary in the use of tuberculin, we believe its use should be extended, and in view of what he says, it is illogical to limit its use as he does.

Dr. Bonney is an advocate of the most pronounced type of the climatic treatment of tuberculosis. For him the ideal climate is found in Colorado, especially in Denver and Colorado Springs. Even in those features which apparently detract from the perfect ensemble, he finds "concealed" desirable features. It would be hard to imagine a more marked contrast than his description of Colorado and the Adirondacks. The latter he says have a comparatively small number of sunny days, moderate humidity, and an abundance of clouds, fog, snow and rain, yet admits that they have a "well-deserved reputation as a place of sojourn for pulmonary invalids." From his description certainly no more unsuitable climate could be found, yet we know that the results obtained there are among the best in any part of the world.

His reiterated advice concerning "regard for infinite detail" in the treatment of tuber-

culosis is to be most highly commended, and we suspect that much of the good he attributes to climatic influences is due to this minute personal attention, which is the keynote of successful treatment in any climate. It would be fairer, and the arguments have more weight, if Dr. Bonney proved by statistical comparison the marked advantages of Colorado over what he considers less favorable regions.

In the treatment of hemorrhage on page 717, Dr. Bonney wisely, we think, advises against the use of all drugs calculated to reduce the volume of blood in the lungs, as worthless and harmful. On page 722, however, he speaks highly of placing ligatures around the extremities, which act by reducing the volume of blood, though the pathologic changes which prevent the contraction of the vessels at the site of bleeding must act with equal force in both cases.

The chapter on Theories of Immunity is the weakest part of the book, and should be omitted in the future, or re-written. The text is far from clear, and many inaccurate expressions are used, such as "toxic infection," "receptor cells," "protective poisons," "bacilli emulsion," etc. If his description of an antitoxin means anything it is that antitoxins consist of an excess of haptophores!

In describing Wright's technique we are told that the film is so spread as to insure even distribution of the cells. This is exactly what we try to avoid, Wright having devised a special method of spreading with the end of a slide for the purpose of pressing the leucocytes to the edges and end of the smear, to facilitate counting.

The *italic* is overworked throughout the book.

The names of Lassar, Delépine, Vallée, Gabbett, Descos and Larrier are misspelled.

It is more easy to pick flaws than to construct a book, but in a work of such general excellence, it is particularly disappointing to find such defects as have been pointed out.

The printing is good, and the illustrations throughout are first class, from the technical, as well as the educational standpoint.

In spite of the defects, and though we may not agree with Dr. Bonney in some of his views, we consider the book a valuable addition to our knowledge of the terrible disease of which he treats. Not only the general practitioner, for whom the book is written, but the specialist will find it well worth careful study.

MAZYCK P. RAVENEL

The World's Gold. A Discussion of the Geological Occurrence of Gold, Its Geographical Distribution, Its Extraction and Methods of Milling, and the Economy of Gold. By L. DE LAUNAY, Professor in the École Supérieure des Mines. Cloth; 5½ x 8½ ins.; pp. 242. \$1.75 net. New York, G. P. Putnam's Sons.

The preface of this work is an interesting thesis on the function of gold in the world's industrial development. According to the author, it is not only the basis of all wealth, but it is "the whole of wealth"; furthermore, it is a great civilizer and one of the most powerful agencies making for the development of the resources of the world.

The chapters on the geological occurrence and geographical distribution of gold are of necessity, in a work of this character, unsatisfactory and far from exhaustive. The same may be said, and with greater force, of the chapter on extraction and dressing of gold ores—practically no definite or clear ideas can be acquired by a perusal of these chapters. However, from the standpoint of the economist, scientific details are not necessary.

The main value of this work lies in the chapter on the Economy of Gold, and it may be said that in this respect it is a positive and exceedingly valuable addition to the literature on the relation of gold to money and commerce.

L. de Launay examines the problem of the future supply of gold from the scientific standpoint and correlates the influence of this supply with prices and the movement of capital from the financial standpoint. Thus he performs the rare service of welding together the technical and economical aspects of the subject.

Taken as a whole, the work is well and logically written and fairly accurate in facts and figures. It is a work which will be read with interest by both technical and non-technical readers, and especially by those interested in the financial aspect of money and metals.

WALTER R. CRANE

On the Witness Stand: Essays on Psychology and Crime. By HUGO MÜNSTERBERG, Professor of Psychology, Harvard University. Pp. 269. New York, The McClure Co. 1908.

Professor Münsterberg writes as the champion of a cause. A new science is taking shape. Fifty laboratories are its servants. It is applied psychology (p. 9). Education, medicine, art, economics and law are its natural fields; but the obdurate lawyer bars it out of the last.

The reader of these essays, who is familiar with the practise of courts, will question if the author gives them sufficient credit for the rules which they have themselves worked out to aid them in the search for truth. His criticisms are addressed to those in which the trial is by jury, and there is no examination of the accused by the presiding judge. The American jurymen is commonly of more than average education and ability, else he would not be found upon the panel. Among twelve such men there will be those who have met, not only the ordinary, but some of the extraordinary experiences of life. They all know what strong emotion is. They are no strangers to the force of temptation, of suggestion, of the association of ideas. They are in one respect, and that an important one, more competent to weigh the value of testimony than a professor of psychology, because they are nearer to the ordinary witness in character and circumstance. They have learned from a lifetime of buying and selling, of giving and obeying orders, of hiring and discharging, of hearing news and telling news, how difficult it is for two men to see or understand a thing in exactly the same way, and how impossible it is for them to describe it exactly in the same way.

The lawyers and judges, too, have been

schooled in certain rules of evidence. Professor Münsterberg is wrong when he says (p. 22) that they hope to get the exact truth, when they ask some cabman how much time passed between a cry and a shot. They know, and the jury know, that what seems to some a space of minutes, will seem to others, and perhaps with better reason, a space of seconds. Witnesses may differ on the size or length or form of a field, "and yet," says the author (p. 33), "there is no one to remind the court that the same distances must appear quite differently under a hundred different conditions." He would have the psychologist intervene, and explain all this to a dozen men whose every-day experience has taught it to them from boyhood.

So when he declares (p. 44) that "the confidence in the reliability of memory is so general that the suspicion of memory illusions evidently plays a small rôle in the mind of the jurymen" and cross-examining lawyer, he discredits their intelligence on quite insufficient grounds.

Professor Münsterberg would have witnesses examined by a psychologist (pp. 46, 62) with regard to their powers of perception and memory, their faculty of attention, their lines of association, the strength of their volition, and their impressibility by suggestion. He does not tell us whether he would have this examination take place in or out of court. If in court, it is obvious that it would greatly multiply the questions for the jury to decide, and be mainly unintelligible to them except as supplying a basis for the examiner's ultimate conclusions: if out of court, it would involve wearisome statements, probably from more than one expert, of the experiments tried, and open the way to a still more wearisome cross-examination. In either case, the prospect of submitting to such an ordeal would make many men and more women unwilling to testify in court, and so tend to dissuade them from letting it be known that they are cognizant of material facts.

The author urges a resort to the association-test, or the automatograph, in the case of those charged with crime; saying that (pp. 82, 124, 132) a guilty man, of course, will not object.

since he can not refuse and yet affirm his innocence. This ignores the settled construction of the provision in all our constitutions that the accused can never be compelled to give evidence against himself.

The effect of suggestion on a witness is spoken of as something to be understood and explained only by a professed psychologist (p. 158). The rule of all Anglo-American courts which excludes questions naturally leading to a desired answer as to a material fact, shows how well jurists have appreciated this particular tendency of the human mind.

The position of the Lombroso school that a criminal, like a poet, *nascitur, non fit*, is pronounced untenable (p. 234). We are all potential criminals; not actually such, largely, because we are afraid of unpleasant consequences, and society has been so kind as to environ us with circumstances favorable to the development of this fear (pp. 238, 250, 266). The clearest sources of pure life are (p. 262) "the motives of private, personal interest between human being and human being."

Disrespect for law the author counts as an important cause of crime. In that view, it is questionable whether he was wise in giving so much space to the psychological aspects of two recent murder trials; that of Moyer (p. 92), in which he made a scientific examination of the main witness for the state and concluded that he was an honest one, though the jury did not believe him, and another in Chicago (p. 163), where a man was hanged upon his own confession, whom Professor Münsterberg, without having examined him, pronounced innocent.

Like all that comes from the author's prolific pen, this book is thoughtful and suggestive. It would be more valuable if, instead of dwelling solely on the aid which psychological experts could render to courts, he had also discussed the practical difficulties which lie in the way.

SIMEON E. BALDWIN

SCIENTIFIC JOURNALS AND ARTICLES

The American Naturalist for February contains the address of Charles F. Cox, president of the New York Academy of Sciences,

on "Charles Darwin and the Mutation Theory." The author presents many facts to show that Darwin was well aware of the tendency of many species to sudden and marked variations, these variations being perpetuated, but that, nevertheless, he was convinced that this was exceptional and extraordinary. Such being the case, he would scarcely have subscribed to De Vries's *dictum* that species and varieties have originated by mutation and at present are not known to have originated in any other way. Robert F. Griggs presents the second, and concluding, part of his article on "Juvenile Kelps and the Recapitulation Theory," the decision being that except as some tendency has operated to change the heritage the history of the individual does recapitulate the history of the race.

The Zoological Society Bulletin for January opens with part two of a paper on the "New World Vultures," by C. William Beebe. This is largely devoted to the California condor, but also contains an account of an interesting experiment to test the sense of smell in the vultures; it seems to be almost lacking, and is best developed in the turkey buzzard. There is an account of how the hippopotamus was moved to the new elephant house and a note giving the weights of the elephants and rhinoceroses. Hunting song birds has not ceased entirely in the vicinity of the park and they are occasionally sought with shot-gun and traps.

The Museums Journal of Great Britain contains, besides its many interesting notes and reviews, "The History of the Ipswich Museum," by Frank Woolnough, and an article by L. Wray, on "The Preservation of Mammal Skins." This is of importance from the fact that the writer gained his experience in the Perak Museum, where he had to contend with the hot, moist climate of the tropics.

The Bulletin of the Charleston Museum for January contains the report of the director for 1908, which notes the good progress made during the year, especially in the development of the library, which is the only free public library in the city.

The Museum News of the Brooklyn Institute for February notes various advances during the year 1908 and a great gain in attendance, the number of visitors at the Central Museum having been 203,940 and at the Children's Museum 117,182, a total increase of 54,000 over 1907. There is an article on "The Games of the Cliff-Dwellers" and another on the almost lost art of "Scrimshawing." A number of "Additions to the Insect Collection at the Children's Museum" are noted and a list is given of zoological charts for loaning to schools.

SOME of the English Museums from time to time issue extremely good handbooks at astonishingly low prices. A recent publication of this kind is the Handbook to the Weapons of War and the Chase in the Horniman Museum, London, written by H. S. Harrison, curator of the museum, and edited by A. C. Haddon. This book of 73 pages describes a great variety of weapons and includes a list of some of the books and papers on the subject in the Museum Library and sells for twopence, or by post, threepence.

In the *Report on the Illinois State Museum of Natural History*, Dr. A. R. Crook, the curator, makes a strong plea for the establishment of a museum worthy of the state of Illinois, showing by statistics and illustrations how much has been done by other states and how much may be done in Illinois.

**THE RIABOUSCHINSKY EXPEDITION UNDER
THE AUSPICES OF THE IMPERIAL RUSSIAN
GEOGRAPHICAL SOCIETY¹**

I AM grateful to the society for the opportunity extended to me to give a brief outline of the organization and aims of the Riabouschinsky expedition. In fact, I believe that you are just as much interested in the results to be attained by this expedition as we are in Russia, because a good part of my investigations are to be made on American soil.

The patron of this expedition is Mr. Theodor Riabouschinsky, a well-known capitalist in Moscow. He is a very young man, and dur-

¹Paper read at the meeting of the American Ethnological Society, November 9.

ing his studies in the Moscow university he paid particular attention to anthropology. He conceived the idea of undertaking a thorough investigation of the Kamchatka Peninsula. The importance of this investigation will be realized when I will tell you that Kamchatka has been under Russian control for about three hundred years and has been visited by many noted travelers, yet very little is known about the country. Up to about fifty years ago Kamchatka was the only open door Russia had to the Pacific Ocean, and at that time the government took some interest in that country; but since the Amour River has been acquired by Russia, the government has neglected that peninsula completely. For this reason the great service rendered to science by a private undertaking will be appreciated.

Mr. Riabouschinsky requested the Imperial Russian Geographical Society to organize at his expense a scientific expedition to Kamchatka. This society organized an expedition consisting of five divisions: Zoological, botanical, geological, meteorological and ethnological. The zoological division is headed by Peter Schmidt, professor at the University of St. Petersburg. He and his four assistants, representing the different branches of zoological science, are to investigate the fauna of Kamchatka. Komaroff, the chief botanist of the Imperial Botanical Garden in St. Petersburg, is the leader of the botanical division. He has four assistants and has to study the flora of Kamchatka and its distribution. The geological division consists of two independent sections—one headed by Krug, a mining engineer, is to study the general geology and topography of Kamchatka; the second section, headed by Konradi of the Russian Geological Survey, is to direct a special investigation of the volcanoes in Kamchatka. The meteorological division, consisting of five members, under the direction of Vlassoff, of the observatory of St. Petersburg, will study the climate of that country. All these four divisions are already on that peninsula, busily engaged in their respective investigations, which, it is presumed, will last about two years.

The ethnological work was entrusted to the writer of this paper. While accepting the invitation to make this ethnological investigation, I proposed that the area to be studied by my department should be extended so as to include the Aleutian and Kurilian Islands. My reasons were that the northern Kamchadal have already been studied by the Jesup expedition, and the southern Kamchadal are already Russianized to such a degree that archeological work alone, and some relics of the former material culture, can give us some direct indications as to the primitive life of the Kamchadal. Even the somatological work becomes uncertain in many localities where the intermixture with Russians was especially extensive. The position of an ethnologist in Kamchatka should not be judged by the standard of a naturalist who undertakes studies there. While nature has not changed there since the Russians came there, this is not the case with man. The old Kamchadal beliefs, manners and customs are disappearing; some traits, in fact, have already vanished, leaving hardly any traces behind. It seemed to me, therefore, that two years of field work among the Kamchadal alone would not be sufficiently remunerative from a scientific standpoint. On the other hand, the ethnology of the Kamchadal can not be investigated, to any great extent, without the study of the neighboring tribes. The Jesup expedition in its endeavors to clear up the history of the American tribes has already investigated the tribes nearest related to the Kamchadals; I refer here to the Koryak, Chukchee and Yukaghir tribes, as well as to some remotely related tribes, such as the Giliak and Ainu. The nearest neighbors of the Kamchadals in the east are the Aleut. You are undoubtedly aware of the fact that the extreme western Aleutian islands are separated from the eastern shores of Kamchatka by only about three hundred miles, in the center of which are situated the Komandorski islands. And the Aleut have as yet not been sufficiently studied. Even the Jesup expedition has not succeeded in studying this most interesting tribe.

Another object of my study is to investigate the former relations of the Kamchadal to the Ainu. This can only be achieved by a study of the Kurilian islands. In order to attain this, I propose to remain only one year in Kamchatka and to devote the other year of my work to the Aleutian and Kurilian islands. In this manner my work will extend outside of the geographical limits within which the other divisions are working. I decided to spend the first year of my studies among the Aleut. To reach the Aleutian islands I found it advisable to take the western route, by way of America, and on this account my party has had to be separated from the other divisions of the expedition.

Concerning the investigations of the Aleut, I can say the same as I said about the Kamchadal. Under the Russian rule they have been Russianized to such a degree that ethnology has lost considerably. Much, however, can be done even now. We must endeavor to reestablish the past by a study of what remains of their old habits and customs, and their former family and social relations and material culture. It will also be very difficult to define the physical type of the present Aleut, considering the extensive intermixture which has taken place between them and the Russians. But their language is still available for study, and it is important to define the relation of the Aleut language to the Esquimo dialects. It is also important to make new excavations, considering that Dall has found traces of different cultures on the Aleutian islands.

The investigations I plan to make consist essentially in a continuation of my work done for the Jesup expedition. I have in view to contribute to the solution of some problems which have already been raised by the Jesup expedition. It is significant that during the period from 1900 to 1902 I have made investigations on Russian territory on behalf of an American scientific institution, and that I am now on my way to carry on an investigation of the same nature on American territory on behalf of a Russian scientific society. May this serve as an additional proof of the

established adage that science is international in its scope. After all, the results of every scientific investigation become common property, irrespective of the nation which undertakes the work.

My route will be about as follows: At Seattle I will embark on December 8 on the steamer *Pensylvania*, reaching Seward within a week. There I shall take another steamer, the *Dora*, which goes directly to Unalaska. I do not know as yet exactly in what manner I shall travel around the Aleutian islands. At present only three islands are inhabited: Unalaska, Atka and Attu.

But for excavation purposes I must also visit some other islands which are not populated at present, but were so in the past. In the spring of 1910 I expect a Russian naval cruiser to come and take me and my party from the Aleutian islands to the Komandorsky islands, and from there to Petropavlovsk in Kamchatka. Kamchatka I intend to study not only along the coast, but also in the interior. In the north I shall try to reach the bay of Baron Korf, and in the south to go as far as Cape Lopatka. Everywhere I shall endeavor to make excavations of old Kamchadal villages. In the spring of 1911 I hope to return to Russia by way of Vladivostock, visiting on the way some of the Kurilian islands.

My party consists of myself and two assistants, one of whom is my wife, who also accompanied me on the Jesup expedition. Mrs. Jochelson will act in the capacity of both physician and somatologist.

In closing I wish to express for myself, as well as for the Russian Imperial Geographical Society, my gratitude to the governmental and scientific institutions of New York and Washington for the assistance and attention shown me while preparing for my journey. The secretary of the interior has kindly granted me, at the request of the Russian embassy, permission to make excavations on American territory. The secretary of the treasury has promised to issue the necessary orders to take me from the eastern to the western Aleutian islands by revenue cutter. The Smithsonian Institution and other scientific bodies have furnished me with many publications, and

maps and also with recommendations, all of which are very valuable to me. The American Museum of Natural History have extended to me their kind hospitality, which I appreciate, and for which I am under obligations to the president and the director of the museum.

WALDEMAR JOCHELSON

ST. PETERSBURG

THE AMERICAN CHEMICAL SOCIETY

THE Baltimore meeting of the American Chemical Society was more largely attended than any previous meeting the society has ever held and was unusually enthusiastic from beginning to end.

The local committee had made special arrangements for the entertainment of the visiting chemists, consisting of banquet and smoker, automobile rides, parties and dinners for the attending ladies, and excursions to Annapolis, to the Maryland Steel Company's works, to the various Baltimore breweries, to Sharp & Dohme's works and to various points of interest around the city. In this respect the city of Baltimore kept fully up to its general reputation for hospitality.

Some four hundred and twenty-five chemists were present and attended the various sectional meetings of the society besides the addresses given in general session.

These general addresses have proved a very attractive feature of recent meetings and those delivered at Baltimore before the whole society were:

"The Untilled Field of Chemistry," by A. D. Little.

"The Use and Abuse of the Ionic Theory," by Gilbert N. Lewis.

"The Work of Werner on the Constitution of Inorganic Compounds," by Chas. H. Herty.

"The Future of Agricultural Chemistry," by H. J. Wheeler.

"The Quantitative Study of Organic Reactions," by S. F. Acree.

"The Classification of Carbon Compounds," by Edward Kreners.

"The Efficiency and Deficiencies of the College-trained Chemist when Tested in the Technical Field," by Wm. H. Nichols.

"To what Extent should College Training Confer Practical Efficiency along Technical Lines?" by Louis M. Dennis.

"The Attitude of Technical Institutions to Post-graduate Study," by Wm. McMurtrie.

To these should be added the retiring addresses

of President M. T. Bogert of the American Chemical Society on "The Function of Chemistry in the Conservation of our Natural Resources," and of H. P. Talbot, vice-president of Section C of the American Association for the Advancement of Science, on "Science Teaching as a Career."

Over one hundred and sixty papers were announced and read before the nine different sections into which the meeting was divided. Many of these papers were of far-reaching interest and the sections were fully attended. It is probable that no one of the sections was more enthusiastic than the recently organized Division of Industrial Chemists and Chemical Engineers, which was in session on four separate days and whose meetings were unusually enthusiastic. The paper of E. G. Bailey, on "Accuracy in Sampling Coal," proved of such great interest to the members that the discussion was allowed to continue for over two hours and the paper of W. H. Walker, describing a new method of quickly finding imperfectly covered spots on tin plate, aroused almost equal discussion and interest among the chemists present.

The Section of Physical and Inorganic Chemistry, the Section of Agricultural and Food Chemistry, the Section of Organic Chemistry and the Section of Fertilizer Chemistry having petitioned the council for permission to organize as divisions of the American Chemical Society the following divisions were authorized and have organized and elected officers: Division of Physical and Inorganic Chemistry, Division of Agricultural and Food Chemistry, Division of Organic Chemistry, Division of Fertilizer Chemistry.

CHARLES L. PARSONS,
Secretary

**THE THIRTY-NINTH GENERAL MEETING
OF THE AMERICAN CHEMICAL SOCIETY
AND THE MEETING OF SECTION C OF
THE AMERICAN ASSOCIATION FOR
THE ADVANCEMENT OF SCIENCE**

THE thirty-ninth general meeting of the American Chemical Society and Section C of the American Association for the Advancement of Science was held at the Woman's College in Baltimore from Tuesday, December 29, to Friday, January 1, 1908-9.

On Tuesday morning Section C was organized and this was followed by the opening session of the American Chemical Society. After the general meeting in the afternoon the following addresses were given before the Section of Chemical Education:

The Efficiency and Deficiencies of the College-trained Chemist when Tested in the Technical Field: WILLIAM H. NICHOLS.

To what Extent should College Training Confer Practical Efficiency along Technical Lines: LOUIS M. DENNIS.

The Attitude of Technical Institutions to Post-graduate Study: WILLIAM McMURTRIE.

This section was well attended and the greater part of the afternoon was spent in the discussion of the papers.

On Tuesday evening a complimentary smoker was given at the Belvedere Hotel by the Baltimore Section of the society. The smoker was preceded by an illustrated lecture on the "Lumiere Process of Color Photography," by William Simon.

On Wednesday afternoon excursions were made through the Naval Academy at Annapolis; through Sharp and Dohme's drug factory, and also the Baltimore breweries.

On Thursday evening a subscription dinner was given at the Belvedere Hotel. This proved to be one of the most pleasant events of the meeting.

On Friday afternoon an excursion was made through the Maryland Steel Works.

On Saturday many of the chemists visited the Bureau of Standards and Geophysical and other laboratories in Washington.

The following addresses were given before the general assembly:

The Function of Chemistry in the Conservation of our Natural Resources: President M. T. BOGERT.

The Untilled Fields of Chemistry: A. D. LITTLE.
The Use and Abuse of the Ionic Theory: GILBERT N. LEWIS.

Science Teaching as a Career: H. P. TALBOT.

The Work of Werner on the Constitution of Inorganic Compounds: CHAS. H. HERTY.

The Future of Agricultural Chemistry: H. J. WHEELER.

The Quantitative Study of Organic Reactions: S. F. ACKEE.

The Classification of Carbon Compounds: EDWARD KREMER.

The following papers were reported before the various sections:

AGRICULTURAL AND FOOD CHEMISTRY

H. J. Wheeler, chairman

Analyses of Milk Products: EDWARD GUDEMAN.

This paper gives comparison of results obtained in the determination of fat, using the standard or official methods and a new method for fat

determination in milk products such as condensed milk, evaporated milk, malted milk, milk powders, milk chocolate, milk cereal products and candies containing milk products or other fats.

The new method suggested is so simplified as to give correct results in the hands of chemists not having special experience in the analyses of such products, besides materially decreasing the time of making analyses. A weighed quantity of the product is dissolved in water or made into an emulsion, the fat and proteids precipitated with copper sulphate, filtered on a fat-proteid free paper, allowed to drain and the damp precipitate on the paper directly extracted with ether. The extracted precipitate is used for making proteid determination by the Kjeldahl method, digesting paper and precipitate. Filtrate from the copper sulphate precipitation is used for determination of sugars and gums. If insoluble starch is present, a weighed filter paper is used and starch determined as difference between total weight of precipitate and proteid and fat found.

Carbohydrates such as starch, dextrines, gums and sugars (cane, maltose, lactose and dextrose) interfere with complete extraction of fat with solvents and in the separation of the fat by the modified Babcock method. Drying the milk product for extraction, direct and after soaking in water, will give low results, due to change in fat during drying (Gudeman, *Proceedings A. O. A. C.*, 1902).

The analyses of milk products containing sugars or cereals or gums are not accurate and it is recommended, therefore, to confine such analyses to the determination of water, ash, fats, proteids, soluble carbohydrates, insoluble carbohydrates and to qualitative examination for starch, dextrine and gum.

The paper reviews the collaboration work done by the A. O. A. C. on condensed milk and evaporated milk during 1907 and 1908.

Effect of Fresh Manure on Denitrification and Plant Growth: E. B. FRED.

This includes the results of field, pot and laboratory experiments with fresh manure containing large amounts of straw. The effect was studied in experiments, where fresh manure was compared with well-rotted manure, with and without the addition of nitrate of soda. The loss due to denitrifying bacteria present in the straw was measured by its effect on plant growth.

The Colorimetric Determination of Nitrates in Soil Solutions containing Organic Matter: W. A. SYME.

Potassium permanganate is added to the hot soil solution, acidified with sulphuric acid, until in excess. The solution is filtered, made alkaline with sodium carbonate and evaporated to dryness on water-bath. The residue is treated with water, filtered and diluted to its original volume. The solution is now ready for the colorimetric determination of nitrates in the usual way with phenol disulphonic acid and ammonia.

There was no nitrate formation by the action of the permanganate on the organic matter.

Change in Composition of Unground Cereals during Storage: SHERMAN LEAVITT and J. A. LECLEBO.

Samples of corn, wheat, barley, oats and rye in the unground state were allowed to stand for two years. Every six months samples were drawn for grinding and analysis. The authors found a gradual change in all of the cereals taken. This change becomes more rapid if the samples are ground before aging. The most marked changes are in the content of total sugar, 70 per cent. alcohol soluble proteid, 5 per cent. K_2SO_4 soluble proteid and Stutzer water soluble proteid. Unground corn lost 60 per cent. of its total sugar in two years and its entire germinative power. There was also evidence of a rearrangement of the proteid molecules.

In general corn, barley and oats in the order given were found most subject to a change of sugar content producing a loss. Wheat showed an increase of sugar in two years.

Corn, barley, rye, wheat and oats in the order given show the greatest proteid change.

The Importance of Experience in the Interpretation of the Results of Chemical Analyses: H. H. HANSON.

Incompletely described methods of analysis, unusual variations in materials under investigation, skillful imitations of many important products, and the personal equation of the operator make necessary the most extreme care in interpreting results of chemical analyses. The importance of check determinations with known substances and of repeated trials of unfamiliar methods is illustrated by reference to work upon paris greens, the search for artificial color in various products and examination of maple syrups and sugars and various kinds of vinegars. Unusual variations in the latter are cited and the importance of physical tests emphasized.

Lead Test in Cider Vinegar Analysis: F. A. NORTON.

Attention is called to the varying emphasis given to the lead test in cider vinegar analysis and the reagents employed. The test is shown to be of particular value in the case of a turbidity only being produced on the addition of neutral lead acetate to the vinegar being examined. The turbidity together with failure of the vinegar to give a copious precipitate is due to the presence of the normally insoluble pectinous constituents of the apple marc due to heating either through fermentation or steaming of second pressings or through the employment of badly fermented and heated apples for the manufacture of the vinegar. Increase in the right-handed polarization and of reducing sugars on inversion gives confirmatory evidence as to the presence of second pressings or employment of badly fermented stock. The neutral lead acetate is shown to be more delicate in its reaction than lead subacetate for the lead test, while the addition of alcohol, which is sometimes advocated, is not permissible as alcohol readily precipitates the pectinous bodies causing the turbidity, thus destroying the value of the test.

Normal Occurrence of Boric Acid in Virginia Peanuts: F. A. NORTON.

Reference is made to previous work showing the presence of traces of boric acid in apples, pears, quinces, grapes, pomegranates, peaches, gooseberries, cherries, oranges and lemons. Also in hops, radishes, lettuce, carrots and sugar beets, the maximum amount of boric acid normally occurring which has been reported being .016 per cent. Reference is then made to work at the National Cannery Laboratory, showing the normal occurrence of boric acid in two lots of Virginia peanuts, the amount being .015 per cent.

To Determine Fat in Sweetened Condensed Milk: C. E. COCHRAN.

Weigh out 25 grams of the sample, dissolve in water and make up to 100 c.c. Transfer 6 c.c. to a double-tube milk flask provided with a small-bore tube graduated to give percentage of fat for 5 c.c. milk. Add 4 c.c. of ether and 4 c.c. acetic acid (80 per cent. or more absolute acetic acid). Acetic acid of this strength will dissolve the curd, but has no effect on the sugar. Place the flask in a vessel of warm water and heat until the ether is expelled. A layer of milk fat will now be seen floating on the surface of a clear and colorless liquid. Fill the flask with hot water, thus raising the fat into the graduated tube. The percentage of fat can now be read, the sample whirled in a centrifugal machine and another reading made. Multiply the reading by four.

The Anti-putrescent Effects of Copper Salts: ALFRED SPRINGER.

The peculiar behavior of the "certified and inspected milk" from the largest dairy impressed some of the chemists of this city with the belief that some antiseptic had been added to cause this milk to remain sweet. The milk commissioners and owners of the dairy in question indignantly denied that such was the case. After a long series of tests I found small quantities of copper salts present in all the bottles of certified and inspected milk coming from this dairy; furthermore, traced its presence largely to a boiler compound used, containing copper salts, which primed over in the sterilizing room. The milk is especially abnormal in never becoming putrescent, and showing, when exposed to the atmosphere peculiar growths of molds, which are described in the paper.

Experiments to show the anti-putrescent effects of copper salts with meat, egg and blood albumin, sewage and other substances are also described.

The Composition of the Oregon Hop: C. E. BRADLEY.

A study of typical hop plants with respect to their requirements of the soil gives values for phosphoric acid similar to those reported by Wolff. Nitrogen and potash are, however, less by one half in Oregon samples. Choice fresh hops yield .48 per cent. of oil by steam distillation. The resin content of sixteen commercially graded samples is reported, choice grades giving from 12.32 to 13.75 per cent. soft resin and from 5.35 to 6.59 per cent. hard resin.

The Effect of Low Temperatures upon B. coli and B. typhosus in Sterilized, Artificially Infected Milk: GEO. W. STILES, JR.

This investigation involves a bacteriological study of sterilized market milk artificially infected with pure cultures of *B. coli* and *B. typhosus*. Ninety small Erlenmeyer flasks containing 50 c.c. each of the infected milk were placed at ordinary ice-box (53°-63° F.), chilling (30°-34° F.) and cold-storage (-5°-8° F.) temperatures.

At intervals of three to four days one flask from each lot was removed and the number of colonies determined by plating on plain agar, being incubated four days at 25°-27° C. The initial bacterial content having been determined, the change in numbers varying from this standard are represented diagrammatically.

At ordinary ice-box temperatures the number of organisms, both *B. coli* and *B. typhosus*, multiply

quite rapidly from a few thousand to many millions. Milk infected with *B. coli* did not coagulate within thirty days, except by heating, which was first observed nine days after infection with a bacterial count of 1,000,000,000 per cubic centimeter and acidity of 4 per cent.

Since the investigations are yet incomplete, further conclusions are not deemed advisable at this time.

Enzymes of Some Lower Fungi: ARTHUR W. DOX.

The enzymes were prepared by growing pure cultures of the molds on a protein-free medium and dehydrating the mycelium by Albert and Buchner's method for "Acetondauerhefe." The *Penicillium* of Camembert cheese was used principally. It was found to contain a protease which digests casein, gelatine and Witte-peptone, but which is without action on ovalbumin, vitellin, fibrin, elastin, edestin and exoelisin. Its greatest activity is at the neutral point of methyl orange. It resembles Cohnheim's erepsin and Ascoli's "glutinae." A hippuric acid splitting enzyme was also found which yielded 64 per cent. of the theoretical amount of benzoic acid in twenty-four hours. Two green molds, *Penicillium chrysogenum* Thom and *Penicillium Roqueforti* Thom, both of which answer to Link's description of *Penicillium glaucum*, yielded in the one case 83 per cent. hydrolysis with sodium hippurate and

in the other case no hydrolysis at all. Attention is, therefore, called to the necessity of using definitely identified organisms to make chemical experiments of any value. The numerous carbohydrate-splitting enzymes found in fungi by previous investigators were due in part at least to a breaking down of glycogen contained in the mold extract.

Some of the Fermentative Properties of Bacteria:

D. H. BERGEY, M.D.

In a previous paper¹ I reported on a number of bacteria studied by myself and Dr. Deehan with regard to the fermentation of saccharose, dulcitol, adonitol and inulin. These carbohydrates were employed because the work of MacConkey indicated that they were of primary importance in the differentiation of bacteria belonging to the colon *aerogenes* group. Subsequent study with regard to the fermentative properties of these bacteria on other carbohydrates demonstrated that an organism without fermentative properties for these four carbohydrates might still not compare with others of similar properties with regard to other carbohydrates. Detailed study has shown that lactose, sorbose, raffinose and dextrin are also of primary importance in the differentiation of this group of bacteria.

I have attempted to ascertain some law concerning the fermentative properties of these bacteria to assist in explaining why one carbohydrate should be acted upon by a particular organism and another carbohydrate of related structure left intact. According to the teaching of Fischer and others, ferments can break up only those carbohydrates that have one or more asymmetrical groups, and in the light of Fischer's teaching the ferment must correspond in configuration to the carbohydrate on which it is acting, in a way similar to the relation of a key to the lock which it opens. We must conceive then that the ferment must likewise possess one or more asymmetrical groups so as to correspond to the configuration of the carbohydrate, or to be enabled to link on to the carbohydrate molecule to form a new chemical combination.

My studies have failed to disclose any constant relation between the carbohydrates fermented by closely related bacteria, and hence no law by which one could foretell what action a certain micro-organism might have on the different carbohydrates.

The Munroe Crucible: WALTER O. SNELLING.

The use of platinum felt as the filtering medium in a crucible of the Gooch pattern was first suggested by Professor Charles E. Munroe, in an article entitled "Filtration with Filters of Metallic Felt" published in the *Journal of Analytical Chemistry*, Vol. 2, part 3, July, 1888.

Crucibles prepared by the method suggested by Professor Munroe have many advantages not possessed by any other type of apparatus used for filtration. These filters retain the finest precipitates, and owing to the fact that no other material than platinum enters into the construction of the filter, no impurity other than this metal can contaminate the filtrate, and thus in very exact work a very great advantage is gained through the use of the Munroe crucible.

A series of tests were described, showing that the porosity of the mat of the Munroe crucible

was many times greater than that of the asbestos mat in crucibles of the usual type. The preparation of the crucible was described, and a number of experiments were mentioned showing the wide range of applications for which the crucible was suited, and the many classes of work in which it has been found to be superior to other types of filtering apparatus.

The Rapid Determination of Moisture in Commercial Products of a Viscous or Semi-solid Consistency: ARTHUR LOWENSTEIN.

The author states that "the method employed consists merely in the application of several well-known principles, viz., the addition of a dehydrating agent of a lower boiling point than water, in which the material to be desiccated is wholly or in part soluble, or at least miscible. The reagent employed is ordinary 95 per cent. ethyl alcohol. In the case of materials containing soluble proteins, the alcohol acts in some cases as a coagulant, and in others as a precipitant, which action facilitates the drying process. A definite quantity of the material is weighed into a metal dish, $2\frac{1}{2}$ inches in diameter, together with a short glass stirring rod, 15 c.c. of alcohol added; stirred thoroughly; evaporated on steam bath; another portion of alcohol added and similarly evaporated. Dish then transferred to jacketed oven at 105° C. and dried to constant weight. Total period of drying, $1\frac{1}{2}$ – $2\frac{1}{2}$ hours. Table gives results of tests on meat extracts, concentrated glue solutions, concentrated tank water, inspissated ox gall, dye-wood extracts, syrups, various kinds of cheese, etc.

An Unusual Incrustation on Generator Coils: E. H. EHRENFELD.

On the generator coils of a refrigeration plant of the absorption type there was formed a hard, semi-crystalline scale about one sixteenth of an inch thick. Its texture was very compact, its density 5.117, and on being tapped it gave almost a metallic sound.

It was formed on the outside of two-inch iron pipes through which steam circulated. The pipes were surrounded by strong aqua ammonia, and it was from this ammonia that the scale was deposited. A part of the circulation system having been constructed of galvanized iron, zinc was taken up by the ammonia and the scale deposited therefrom contained over 90 per cent. of zinc oxide.

FERTILIZER CHEMISTRY SECTION

F. B. Carpenter, chairman

- Some Points of Interest in Connection with Present Fertilizer Laws and Proposed Fertilizer Legislation*: ARTHUR LOWENSTEIN.

The author first indicates the points which are

at present uniform in the various state fertilizer laws. He next points out in detail the lack of uniformity in these laws, and states that this is due not so much to lack of uniformity in the basic principles of the laws, but rather in the elaboration of the principles, and the mode of expression of the details. Quotations are made from the 1907 report of the Committee on Fertilizer Legislation of the A. O. A. C., in which this committee favors national fertilizer legislation, after certain specified difficulties have been overcome. The point next discussed is, if a national law were enacted, whether it would bring about the harmony and uniformity desired or not. The author points out why, in his opinion, it would not. He proposes a uniform state fertilizer law and recommends that a committee be selected by the Division of Fertilizer Chemists of the American Chemical Society to confer with similar committees from the A. O. A. C., National Fertilizer Association and the Association of Agricultural Colleges and Experiment Stations, with a view to drafting a uniform state fertilizer bill—all parties concerned being represented on this joint committee. Then if a national law is desired or necessary for the control of interstate commerce, work for the adoption and passage by congress of this uniform law.

Potash Experiments in Factory Work showing Heavy Loss by Official Method and Possible Means of Preventing this Loss: J. E. BROCKENRIDGE.

A brief history of the work of the Association of Official Agricultural Chemists on potash during recent years, showing loss of potash by official method.

Methods used to find this lost potash explained with results on thirteen samples. Some methods used:

No. 3. (a) Same as Carpenter method, except 1 per cent. citric acid solution was used for solvent instead of 5 c.c. HCl in 300 c.c. water.

No. 11. Washed 2 grams on 11 cm. filter with small portion of hot water into a 200 c.c. flask to about 175 c.c., when no effluorid or soluble sulphate should be left in residue on filter. Add .6 gram citric acid to flask, heat contents of flask to boiling, add ammonia and ammonium oxalate and proceed as in official method.

No. 12. Same as No. 11, only use 3 c.c. HCl in place of .6 gram citric acid.

No. 13. Same as No. 11, only do not add any citric acid.

Determination of Acetanilid in Hydrogen Peroxide Solutions: ELWYN WALLER.

In a side neck flask of 200 c.c. capacity, place about half a stick of caustic potash or soda (6 to 7 grams). Add about 20 c.c. of water to dissolve, and then 25 to 30 grams of granulated metallic zinc. Then add a measured amount, not over 50 c.c. of the solution to be tested. Connect the flask on the one side with a flask to supply steam, arranging the tube to deliver steam near the bottom of the solution; connect on the other side with a condenser. The condenser should deliver into a Peligot bulb tube or some other arrangement by which the distillate is immediately brought in contact with moderately strong hydrochloric acid.

Raise the heat on the flask slowly, and when nearly half of the contents have distilled over, start the steam to passing through. The end of the distillation is a matter of guess. When the anilin is coming over in quantity, fumes are to be seen in the receiver, but for the last portions they can not be seen. When it is judged that all has come over, detach the receiver and catch what comes over later in a fresh receiver or a beaker, and titrate it separately.

To prepare the volumetric bromine solution, dissolve 25 grams of caustic potash in 20 to 40 c.c. of water, cool, and add liquid bromine until it appears supersaturated. Then dilute to about 200 c.c. and boil out excess of bromine (judged

by the color). Cool, and dilute to one liter. This should give a solution of which 1 c.c. = nearly 0.01 gm. acetanilid. Standardize by means of a solution containing 0.5 gm. acetanilid in 200 c.c. of water, using 30 to 50 c.c. lots at a time, treated either by distillation on the manner above given, or by boiling with strong hydrochloric acid. Either method was found to give the same result with the same amount of acetanilid.

The method was tested by first distilling known quantities of the sample and titrating the distillate, then adding known amounts of acetanilid to the same quantities of the sample, and distilling. The distillates took just the additional amount required by the acetanilid added.

The presence of acetanilid was indicated by obtaining the isonitrit reaction on the original sample.

Recent Developments in Preparations for Administering Sulphur: ELWYN WALLER.

This paper discusses the reasons why attempts are being made to obtain sulphur in an unoxidized but soluble condition. The therapeutic effects of sulphur seem to be inversely proportional to the degree of oxidation.

Sulphur in solid form does not lend itself readily to absorption. The ordinary solvents of sulphur have therapeutic effects of their own and are not desirable for use.

Lac sulphuris leaves much to be desired. These facts have caused the appearance of preparations of colloidal sulphur. It is claimed these are the equal of lac sulphuris and are soluble in water.

Analysis of two such preparations are as follows (results were in grams per 100 c.c.):

Total sulphur	3.05
Lime	1.51
Residue on evaporation	4.94

Lime appeared to be the only base, and no sulphate was present, the sulphur was probably present as in the lac sulphuris.

A second sample soluble in water contained sulphur probably as sodium sulphite. This sample contained resin probably as solvent for the sulphur. The presence of hydrogen sulphide could not be established in either sample.

INORGANIC CHEMISTRY SECTION

Charles H. Herty, chairman

Denudation in the United States: R. B. DOLE and H. STABLER.

This paper presents computations of the rate at which the earth's crust is being moved as solid particles carried in suspension by streams and as matter carried in aqueous solution. The computations are based on twenty years' stream gauging work at 1,500 stations and about 5,000 water analyses by the Water Resources Branch of the U. S. Geological Survey, supplemented by stream gauging data of the Engineer Corps, U. S. A., and the Weather Bureau and by some miscellaneous analyses from state and municipal reports. Except the estimates for the Northern Pacific, Great Basin and Hudson Bay areas, for which the data are rather meager, the figures are believed to be within twenty per cent. of the correct average values. Estimates for over one hundred secondary drainage basins were computed.

If denudation in the Great Basin is taken as zero, the figures for the entire United States are as follows: Tons of solids removed per square mile per year, dissolved, 87; suspended, 166; amounting to a total of 270 million tons of dissolved and 513 million tons of suspended matter per year; equivalent to 1,330 millionths of an inch per year, or one inch in 760 years.

A Spectroscopic Method for Determining Small Amounts of Lithium: W. W. SKINNER.

The separation and determination of lithium, when present in very small amounts, or when the ratio of sodium and potassium to lithium is high, are accomplished with very considerable difficulty. This method proposes the use of the spectroscope under definite conditions for this purpose, the idea being that the brilliancy and length of duration of the lithium spectrum are, within certain limits, proportional to the quantity of material introduced into the flame.

Classification of the Elements for Arranging References to Articles: A. L. VOEGE, Concilium Bibliographicum, Zurich, Switzerland. (Presented by W. C. Bray, Massachusetts Institute of Technology, Boston.)

Mr. Voegé has been engaged for a number of years in adapting the Dewey system of classification to the subject of electro-chemistry. He desires to use a classification of the chemical elements that will be satisfactory to chemists, and is

anxious to receive expressions of opinion from the American Chemical Society and its individual members on the four different classifications which he has prepared. In two of these the elements are separated into metalloids and metals; in the other two the ordinary periodic system, and the Werner periodic system, respectively, are followed. After considerable discussion, the matter was referred to the council of the society. Circulars describing the different arrangements, which arrived too late for distribution at the meeting, may be obtained from Mr. Bray.

ORGANIC CHEMISTRY SECTION

S. F. Acree, chairman

Preparation of Bensophenone: J. BISHOP TINGLE and W. W. HOLLAND.

It is well known that the interaction of gases at moderately high temperatures is largely influenced by apparently small variations in the physical state of the containing vessel. These effects

are usually described as "catalytic," but it is obviously very difficult in many cases to distinguish between a "catalytic" influence and one due only to an alteration in the thermal properties of the surface of the container. In the hope of throwing some light on the subject we have investigated the production of benzophenone by the distillation of calcium benzoate in a current of carbon dioxide. The calcium salt was mixed intimately with the substances mentioned below, the figures give the percentage yield of benzophenone. Unglazed porcelain, 30.4; carbon from arc light rods, 40.9; iron filings, 45.0; calcium carbonate and iron filings, 54.5; calcium carbonate and arc light rods, 50.0. These results are the mean of closely agreeing duplicates and express the yield percentage of the theoretical. The yield of benzophenone from benzene, aluminium chloride and benzoyl chloride is 42.8 per cent., according to Gattermann.

Studies in Nitration—VI., Synthesis of Certain Nitranilides: J. BISHOP TINGLE and C. E. BURKE.

Work is in active progress on the synthesis of a number of nitrophenylamides, nitrophenylimides and nitrophenylamidic acids from *o*-, *m*- and *p*-nitraniline. In this manner it is hoped to identify some of the many compounds prepared by the senior author and Dr. F. C. Blanck by the nitration of the corresponding aniline derivatives. A description of the individual compounds thus far synthesized will appear in due course.

Aniline Derivatives of Certain Unsaturated Dibasic Acids of the Aliphatic Series: J. BISHOP TINGLE and S. J. BATES.

It has been shown by the senior author and his collaborators that succinilic acid, $C_4H_5NHCOC_2H_4CO_2H$, when treated with aniline yields succindianilide, $C_6H_5NHCOC_2H_4CH_2CONHC_6H_5$, whereas phthalanilic acid, $C_6H_5NHCOC_6H_4CO_2H$, under similar conditions is converted into the anil,

The investigation has now been extended to the aniline derivatives of maleic, fumaric and malic acids. Several new compounds have been prepared. A study is being made of the action of various amines on fumar-, male- and malanilic acids,

and $C_6H_5NHCOC_2H_4(OH)CH_2CO_2H$, respectively.

Rearrangement in the Phthalamidic Acid Series—

IV.: J. BISHOP TINGLE and B. F. PARLETT BRENTON.

The work of Bishop Tingle and his collaborators on this subject has been extended. Phthal-di-phenylamidic acid, $(C_6H_5)_2NCOCC_6H_4CO_2H$, when heated with pyridine at 100° gives dipyridinium phthalate, in 109° . Aniline transforms the acid into phthalanil,

whereas by the action of β -naphthylamine a mixture of phthalanil and phthal- β -naphthylamidic acid, $C_{10}H_7NHCOC_6H_4CO_2H$, is obtained. The following new acids have been prepared by the method described recently by Bishop Tingle and Rolker.¹ A study is being made of the action on them of various amines. Phthalphenyl- β -naphthylamidic acid, $C_6H_5N(C_{10}H_7)COC_6H_4CO_2H$, m. 115° . Phthal-*p*-chlorophenylamidic acid, $ClC_6H_4NHCOC_6H_4CO_2H$, m. 180° . Phthal-diisobutylamidic acid, $[(CH_3)_2CHCH_2]_2NCOCC_6H_4CO_2H$, m. 153° . The product from diisooamylamine was tarry. Ethylaniline and methylaniline yielded the diamides $C_6H_5[CON(C_2H_5)C_6H_5]_2$ and $C_6H_5[CON(CH_3)CH_3]_2$, respectively, m. 144° and 181.5° . Two compounds have been prepared from benzidine and phthalic anhydride, both melt only at high temperatures. One appears to be the diamide or imide,

or

The other has not yet been investigated. *p*-amino-benzoic acid gives the dibasic acid, $HO_2CC_6H_4CONHC_6H_4CO_2H$, m. 271° .

The action of carbamide and its substitution products on phthalic anhydride has been made. It is found to take place according to the equation,

The compounds produced when $R=H$, C_6H_5 , $C_6H_5CH_2$, CH_3 and C_2H_5 have been investigated. Phenylthiocarbamide behaves in a similar manner, NH_3 and CO_2 being evolved. Ethylidenecarbamide

¹ *Jour. Am. Chem. Soc.*, 30, 1882, 1908.

gives a tar. Form- β -naphthylide and phthalic anhydride yield formic acid and phthal- β -naphthyl-imide.

The Synthesis of Orthohydroxyazobenzene: Wm. McPHERSON and H. J. LUCAS.

The synthesis of orthohydroxyazobenzene by the saponification of the compound obtained by the action of unsymmetrical benzoyl phenylhydrazine on orthobenzoquinone was described. The bearings of this synthesis on the constitution of the orthohydroxazo compounds was also discussed.

Occurrence of Diterpenes in Camphor Oil: ALFRED HOFFMAN.

The so-called "blue, thickened" camphor oil of commerce, which consists of the highest boiling parts of camphor oil, contains in its highest fraction a few per cent. of a hydrocarbon $C_{20}H_{32}$. Purified by distillation over metallic sodium, it is a colorless, mobile liquid of faint odor and the following physical properties: b. 20 mm. = 195–205°, b. 760 mm. = 315–320° with slight decomposition, $n_D^{20} = +6.49'$, $d_4^{24} = 0.902$, $n_D^{25} = 1.5024$, molecular refraction for $C_{20}H_{32}$ with three double bonds, found 88.94, calculated 88.77. This would point to its being bicyclic. It does not resinify on standing, can be distilled with steam and is unsaturated toward potassium permanganate and bromine, adding about six atoms of the latter. This seems to be the first instance of a hydrocarbon with such a high boiling-point being found in a natural essential oil.

The Condensation of Acetone with Calcium Oxide: ALFRED HOFFMAN.

The formation of mesityl-oxyl, isophoron and the xylitons from acetone under the influence of calcium oxide has been studied by a number of chemists and the constitution of the products established. The present article deals with the mechanism of the reaction. Briefly, it was found that the simplest condensation product, mesityl-oxyl, was formed first, and from it alone or with acetone the more complicated ones. It was also shown that the first step in the reaction in all cases is an aldol condensation under the influence of the small quantities of calcium hydroxide usually present as impurity. Then water is split off to form the known condensation product. Thus, with perfectly pure calcium oxyl no condensation takes place, even on heating under pressure. In the simplest case, that of acetone to mesityl-oxide, the intermediate product could be isolated and was shown to be the alcohol diacetone which has already been described as a product of the action of alkalis on acetone.

5-Brom-2-Aminobenzoic Acid: ALVIN S. WHEELER.

Trichlorethylidene- α -aminobenzoic acid on bromination in glacial acetic acid gives a high yield of 5-brom-2-aminobenzoic acid which is converted into the free base by water. Direct bromination of anthranilic acid under like conditions gives a less pure product. A detailed comparison of the two methods will soon be completed.

Fixation of Labile Hydrogen Atoms by Chloral:

ALVIN S. WHEELER and STROWD JORDAN.

The condensation of chloral with primary aromatic amines gives compounds of the type $CCl_3CH(NHPh)_n$. Substituted amines may be used, but these are limited to those containing not more than two negative elements or groups in the benzene nucleus. All such compounds on bromination split off chloral and give brominated amines. A quantitative study is being made, comparing this method with the direct bromination of amines. The reactions proceed best in glacial acetic acid.

The Anhydride of Chlorterephthalic Acid: JOHN E. BUCHER.

This acid easily forms an anhydride $(C_6H_4ClO_2)_n$ on treatment with acetic anhydride. Molecular weight determinations indicate that the value of n is very high.

The Oxidation of 1-Phenylnaphthalene Derivatives to Benzenepentacarboxylic Acid: JOHN E. BUCHER.

A number of anhydrides obtained by the action of acetic anhydride on phenylpropionic acid were oxidized to benzenepentacarboxylic acid. This reaction shows that they are derivatives of 1-phenylnaphthalenedicarboxylic anhydride. In the final oxidation which was carried on in fuming nitric acid, it was necessary to use manganese nitrate as a catalytic agent.

PHYSICAL CHEMISTRY SECTION

Gilbert N. Lewis, chairman

The Behavior of the Nickel Anode: E. P. SCHOCH.

Starting at the equilibrium potential of nickel in neutral nickel sulphate solution, and polarizing anodically with gradually increasing current densities, the author found that nickel showed what may be called "normal" anodic behavior with very small current densities, but that with larger current densities the active surface appears to be diminished. This diminution of the active surface is due to the discharge of oxygen; and the whole behavior of the nickel anode with large current densities is due to the relation of the areas of the active to the impaired spots. This presents the phenomenon of porosity in a new light.

The Temperature Coefficient of the Conductivity at Infinite Dilution: JOHN JOHNETON.

Value of Λ , at a series of temperatures ranging between 0° and 156° were obtained for a number of salts by extrapolating with the aid of the function $1/\Lambda = 1/\Lambda_\infty + K(CA)^n$, values of n being chosen so that the graphs were nearly linear. From these were derived values of l , the mobilities of the separate ions. On plotting the values of $\log l$ at the various temperatures against the logarithms of the numerical values of the fluidity of water at the corresponding temperatures, straight lines were obtained for all the ions investigated, with the exception of H^+ and OH^- ,

where, indeed, abnormality might be expected, as these two ions occupy a quite especial position when water is the solvent. For the others (thirteen in number, including uni-, di-, tri- and quadrivalent ions), the derivations from linearity are not greater than the error of the separate determinations. Thus this method presents a very convenient means of obtaining the value of l at any intermediate temperature, or of calculating its temperature coefficient, since the temperature coefficient of the fluidity of water is known and may be expressed by a fairly simple formula.

The Change in Refractive Index with Temperature—I.: K. GEORGE FALK.

The refractive indices for the three hydrogen and the sodium lines and the density of diisomyl, *n*-heptyl alcohol, benzyl alcohol, dimethylaniline, *n*-butyric acid and acetylacetone were determined at a large number of temperatures between 20° and 70°. The variation was found to be a straight line function of the temperature for all. The change in the refractive powers, using the expressions $n^2 - 1/d$, $n - 1/d$, $n^2 - 1/(n^2 + 2)d$, were also calculated. Ethyl acetate gave results indicating a change in the equilibrium between the tautomeric forms at higher temperatures.

A Modified Oxyhydrogen Gas Coulometer: J. W. TURBENTINE.

The Walter-Neumann, single tube, oxyhydrogen gas coulometer, with adjustable leveling tube, has been modified, so that the platinum electrodes, in the old form fastened to a short length of platinum wire which was sealed in the glass walls of the coulometer and terminated on the outside in a small loop, are sealed in glass tubes and are inserted into the coulometer through rubber stoppers held in side arms.

Objectionable features of old form: (1) Electrical connection was made with coulometer by hooking wires in the loops. This gave poor contact and high local resistance and (2) consequent heating which caused alternate expansion and contraction, and soon resulted in the cracking of the glass and the breaking out of the electrodes, (3) or the platinum loops soon broke off. (4) In either case the apparatus became useless and the platinum electrodes had to be discarded.

Advantages claimed for the modified form: (1) Electrodes are adjustable and (2) may be removed and cleaned. (3) Due to the elimination of the fragile seal in the wall of the main tube, the apparatus is more durable. (4) In case of breakage, the platinum parts are not "scrapped," but are transferred to a new tube. This requires the

purchase in such a case of glass parts only. (5) Electrical connection is made through a length of copper wire. Good contact may then be got by means of screw connectors.

The Rapid Precipitation of Metals on Gauze Cathodes with Fixed Electrodes: JOHN T. STODDARD.

Cadmium, copper, nickel, silver, zinc and probably other metals may be quantitatively precipitated for their solutions upon a fixed gauze cathode, with a fixed anode in about the same time as that required when rotating electrodes are employed. The current used is about the same as in the latter method.

The cylindrical cathode, 3 cm. in diameter and 3 cm. high, is made of platinum gauze, described by the maker as 52-mesh and made of 0.004 inch wire. Its total surface is calculated to be about 40 sq. cm. The anode is a cylinder of platinum foil, about 2.5 cm. high and of a diameter which may vary between 0.5 and 1.2 cm.

It is placed concentrically within the gauze cathode. The electrolysis is carried out in a 80 c.c. beaker with about 50 c.c. of solution, in order to gain the advantage of concentration. The current strength may vary within wide limits in most cases without influencing the character of the deposits, but the time is greatly shortened only when comparatively high currents are used.

It appears that the more or less troublesome and expensive arrangements for rotating one of the electrodes, or of agitating or rotating the solution by mechanical means or by the use of a magnetic field are quite unnecessary for rapid and complete precipitation.

The character of the deposited metals is excellent, and entirely satisfactory analyses have been made by the method described above.

The Rapid Precipitation of Metals in a Mercury Cathode with Fixed Anode: JOHN T. STODDARD.

Cadmium, copper, nickel, silver, zinc and probably other metals can be precipitated in a mercury cathode with a fixed anode in substantially the same time as that required with the use of a rotating anode. The anode is a flat spiral of platinum wire, and it is placed 1.05 cm. from and parallel to the surface of the mercury in a 50 c.c. beaker. The cathode connection is made by a platinum wire, which is protected from the solution by a small glass tube sealed to it 2-3 mm. from the end, which dips into the mercury.

The solution may have any volume from 10 c.c. to 80 c.c. The strength of current is limited only by the danger of loss from too violent boiling of

the solution. About 40 g. of mercury are used as cathode.

The following table shows the time necessary for complete precipitation of the metals:

Metal	Approx. Amount	Current Strength	Time in Minutes
Cadmium	0.21 g.	5 Amp.	10
Copper	0.4	4	8
Nickel	0.2	6	12
Nickel	0.5	7	15
Silver	0.5	8	7
Zinc	0.4	6	15

Analyses made by this method give satisfactory results, concordant with those made from the same solutions with gauze cathode and fixed anode.

Some New Laboratory Apparatus: JOHN T. STODDARD.

1. The wire-test-tube holder, described by the writer in the *Journal of Analytical Chemistry*, January, 1890, is used as the clamp on a light stand. The clamp is adjustable at any angle and up to 10½ inches in height above the table. The support is well adapted to many services in the laboratory and has great stability from the special design of its base.

2. A funnel support which fits on the above stand consists of circular plate of aluminium with openings for the reception of four funnels. The special base of the stand insures stability for a much greater load than the funnels when full of solution. Its chief advantage is compactness.

3. A wire dish holder, which grasps an evaporating dish by the edge and holds it securely.

Abstracts have not been received for the following papers:

A New Method of Determining the Partial Vapor Pressures of Binary Mixtures: M. A. ROSANOFF and ARTHUR B. LAMB.

On the Partial Vapor Pressures of Binary Mixtures: M. A. ROSANOFF and C. W. EASLEY.

Recent Evidence for the Existence of Hydrates in Aqueous Solutions: H. C. JONES.

A New Law concerning the Vapor Pressures of Binary Mixtures: M. A. ROSANOFF.

On the Duhem-Margules Equation as applied to Binary and Ternary Mixtures: WILLIAM EDWARD STORY.

Preparation of Pure Hydrogen and the Elimination of Oxygen: GEO. A. HULETT.

A Maximum Volt Meter: W. LASH MILLER.

The Relations between Viscosity and Fluidity: EUGENE C. BINGHAM.

A New Method of Measuring Association by Means of Fluidity Data: EUGENE C. BINGHAM.

A Simplification of the Cytological Process Method for Deriving Thermodynamic Equations: E. W. WASHBURN.

Cuprous Hydrosulfide: W. D. BANCROFT.

Osmotic Studies: L. KAHLENBERG.

Crystallization through Membranes: J. H. WALTON.

An Explanation of the Negative Coefficient of Expansion of Silver Iodide: GRINNELL JONES.

The Significance of certain Numerical Relations in the Sugar Group: C. S. HUDSON.

SOCIETIES AND ACADEMIES

THE TORREY BOTANICAL CLUB

THE meeting of December 8, 1908, was held at the American Museum of Natural History, President Rusby in the chair. About seventy-five persons were present. The announced scientific paper of the evening on "Mechanical Response of Plants" was then presented by Sir Jagadis Chunder Bose, professor in the Presidency College of Calcutta and author of "Response in the Living and Non-Living," "Plant Response as a Means of Physiological Investigation," etc. The presentation of the subject was accompanied by an exhibition of some of the ingenious and delicately

contrived apparatus constructed by Professor Bose for the purpose of measuring and recording the responses of plants to various stimuli. Following is an abstract of the paper compiled from notes furnished by Professor Bose:

The effect of stimulus impinging on a responding tissue is to induce a fundamental molecular derangement. This condition of derangement constitutes excitation. On the cessation of stimulus, there is a slow recovery, the tissue returning to its original condition. This molecular reaction is itself beyond our scrutiny, but it may be shown that we can gauge its intensity and extent by the observation and record of certain concomitant changes induced by it in the responding tissue. Among these are (1) changes of form, manifested as mechanical response, and (2) changes of electrical condition, which may be recorded as electrical response.

The intensity of the responsive change will obviously depend on the two factors of strength of stimulus and physiological condition of the tissue. Hence, when stimulus is constant, the amplitude of response gives us a measure of the physiological condition. Now we know that the changing environment must induce unknown changes in this physiological condition, of which there is no outward sign. But we are here enabled to make the plant itself reveal its condition, by the reply it makes to the blow of a stimulus. A stimulating agent will exalt, and a depressing agent diminish or abolish, this response. We have thus a means of attacking the deeper problem of the physiological variation in an organism.

The speaker had been able to overcome the numerous difficulties which occur in connection with the automatic recording of the mechanical response of the plant, by devising three types of instrument. These are (1) the oscillating recorder, (2) the optical lever and (3) the balanced cressograph.

In the oscillating recorder, the recording lever is made of light aluminum wire and is suspended vertically on jeweled bearings. This lever is L-shaped, and the shorter arm, at right angles to the longer, is attached to the responding leaf. The great advantage conferred by the oscillating recorder lies in the fact that the friction of the writing point against the recording surface is practically eliminated. The source of friction in such arrangements arises from permanence of this contact. In this instrument, however, the writing lever is virtually free, except for the brief intervals in which the smoked glass surface is brought into periodic contact with it. For these records,

the glass surface moves in a vertical plane by means of clockwork, and a minute oscillation to and fro is given to it by the agency of an electromagnetic arrangement. The period of this oscillation is, say, one fifth of a second, and the record is thus made to consist of a series of dots, separated by time-intervals of one fifth of a second. Thus we can see the time-relations of the curve at a glance.

For responsive movements of minute leaflets the speaker employed the optical lever. By use of this a very high magnification is possible. The record is made on a traveling photographic plate by the spot of light reflected from the optical lever, connected with the responding plant.

For the instant detection of the effect of stimulus on the rate of growth, the balanced crescograph is used. Here a balanced and stationary point of light undergoes a sudden movement up or down, according as the rate of growth is enhanced or depressed by the action of an external agent.

In order to study the effects of external agencies on physiological excitability, it is first necessary to obtain a series of normal responses under stimuli of uniform intensity and duration, applied at regular predetermined intervals. This is accomplished by means of the automatic stimulator, in which an expansible fan periodically closes the exciting circuit. The intervals between successive applications and the period of stimulation are, in this instrument, capable of adjustment at will.

In a complete curve of response of the sensitive leaf or leaflet of *Mimosa* or *Biophytum sensitivum*, we find (1) a short horizontal line representing the latent period, (2) an up-curve showing attainment of maximum reaction; followed by (3) a down-curve representing the recovery. The latent period in a vigorous *Mimosa* is about .24 second. The effect of fall of temperature or fatigue results in the prolongation of this latent period to .3 of a second in the former and .58 in the latter case. The maximum fall of the leaf was attained in 1.5 seconds. Complete recovery takes place in 6 minutes in summer and in 18 minutes in winter. In a leaflet of *Biophytum*, the maximum fall is attained in .5 of a second and full recovery is reached in 3 minutes. The excitatory fall of the leaf takes place when stimulus is applied at or near the responding point. Seen from different points of view, this reaction will appear as a diminution of turgor in the pulvinus, constituting a negative turgidity-variation, or a shortening or contraction of the more excitable lower half of the pulvinus. Electrically speaking, this reaction will

have its concomitant in an electrical variation of galvanometric negativity. It is convenient to include all these excitatory symptoms together under the single term *negative response*. Here, however, we may describe a responsive change of precisely opposite character, which takes place under definite conditions. This *positive response* consists of an erectile movement of the leaf; a positive turgidity-variation, expansion, and an electrical change of galvanometric positivity. The occurrence of this positive response may be demonstrated, in *Mimosa*, by applying stimulus at a point distant from the responding organ. In a certain experiment, this positive or erectile response occurred .6 second after the application of a stimulus, and was followed, 2.8 seconds later, by the normal excitatory fall of the leaf. Here we have a response which is *diphasic*, positive followed by negative. When stimulus is moderate, and applied at a still greater distance, the response evoked is positive alone. These facts obtain universally, and from them we derive the following law of direct and indirect stimulation: *The effect at the responding-region of a strong stimulus transmitted to a short distance, or through a good conducting channel, is negative. The effect transmitted to a great distance, or through a semi-conducting channel, is positive.*

Responsive movements, like those of the "sensitive" plants so-called, can be detected also in ordinary plants. It will be noticed, in *Mimosa*, that the responsive movement is made possible by the unequal excitability of the upper and lower halves of the pulvinus, the movement being determined by the greater shortening or contraction of the lower. If now we take a hollow tubular organ of some ordinary plant, say the peduncle of daffodil, it is clear that the protected inner side of the tube must be the more excitable. When this is cut into the form of a spiral strip, and excited by means of an electrical shock, we observe a responsive movement to take place by *curling*, due to the greater contraction of the inside of the strip. This mechanical response is at its maximum at that season which is optimum for the plant. When the plant is killed, its response disappears.

In *Mimosa*, under continuous stimulation, there is a fatigue-reversal, the responsive fall being converted into a movement of erection. The same thing happens in the response of ordinary plants, when the first contractile movement of the spiral, for instance, is reversed, under continuous stimulation, to an expansive uncurling.

An important series of observations is that on the modification of response by the tonic condition

of the tissue. When the condition is sub-tonic, response is by the abnormal positive, instead of the normal negative, reaction. A strong or long-continued application of stimulus, however, converts this abnormal positive into normal negative.

Another important phenomenon is that for which the name of *multiple response* has been suggested. When the stimulus is very strong, the response is often not single, but repeated, or multiple. Excess of stimulus is thus seen to remain latent in the tissue, for rhythmic expression later. This storage of energy from the environment may in some cases be so great as to cause the continuance of rhythmic activity, even in the absence of immediate stimulation. We thus obtain a natural transition into so-called spontaneous or autonomous movements.

The various peculiarities of the spontaneous movements exhibited by *Desmodium gyrans*, or the telegraph plant, may be studied in the automatic record taken by the optical lever. The rhythmic tissues of the plant are then found to have characteristics which correspond to those of similar tissues in the animal. Lowering of temperature enhances the amplitude and diminishes the frequency of pulsation, in the rhythmic cardiac tissue of the animal. The same is found to be true of the pulsatory activity of *Desmodium gyrans*. The effects of various drugs are also very similar. The first result of the application of an anæsthetic like ether is to evoke a transient exaltation, followed by depression and arrest. Poisonous gases also induce a continuous depression of activity. A strong poisonous solution, again, induces a rapid arrest of pulsation.

It has thus been shown that by the waxing and waning of response, the variations in the plant's physiological activity, under changing external conditions, may be gauged. It has been shown also how numerous and varied are the factors that go to make up the complexity of plant-responses. It has been shown that stimulus may be modified in its effect, according as it is direct or indirect, and feeble, moderate or strong. The modifying influence of the tonic condition of the tissue has also been shown, according as this is normal, sub-tonic or fatigued. In the numberless permutations and combinations of these varied factors lies the infinite complexity of the responsive phenomena of life.

After a discussion of Professor Bose's paper by Doctors Rusby, Richards and Pond, the meeting of the club was adjourned to the second Tuesday in January.

MARSHALL A. HOWE,
Secretary pro tem.

THE ASSOCIATION OF OHIO TEACHERS OF MATHEMATICS AND SCIENCE

THE association held its annual meeting in the Chemical Laboratory of the Ohio State University, December 29 and 30, 1908. The attendance of all meetings was very gratifying. The following program was carried out:

TUESDAY, DECEMBER 29, 1908, 1:30 P.M.

General Session

Business.

Mathematics Section

"The Mathematical Club in the High School; its Use as a Supplement to the Work of the Recitation," by J. C. Boldt, department of mathematics, East High School, Dayton.

"On the Nature of Mathematical Knowledge," by F. E. Miller, professor of mathematics, Otterbein University.

Round table.

Science Section

"Physics as a Factor in Forming Character," by C. M. Brunson, department of physics, Central High School, Toledo.

"The Narrow Path or the Broad?" by H. E. Newman, department of chemistry, Walnut Hills High School, Cincinnati.

Round table.

WEDNESDAY, DECEMBER 30, 9:00 A.M.

General Session

Business.

"The Purification of Drinking Water," by C. W. Foulk, department of chemistry, Ohio State University.

Mathematics Section

"Should Mathematics be Taught as a Basal Science or a Tool of Science?" by Paul Bieford, professor of mathematics and astronomy, Buchtel College, Akron.

"Should the Seventh to Tenth Grades be a Unit in Mathematics?" by R. L. Short, department of mathematics, Technical High School, Cleveland.

Round table.

Science Section

"An Apparatus for Demonstrating Wave Motion," by Fred J. Hillig, professor of physics, St. John's College, Toledo.

Experiments and demonstrations.

Round table.

WEDNESDAY, DECEMBER 30, 1:30 P.M.

Excursion to filtration plant now operated by the city of Columbus.

RALPH W. BUCK,
Secretary
DAYTON, OHIO

NORTH AMERICA AND EUROPE: A GEOGRAPHICAL COMPARISON¹

NOTHING could surpass my curiosity when I landed for the first time in North America, a new world, separated from the old one by a great ocean. As a geologist, I knew that similar rocks formed the land and that similar surface features would occur, but as a geographer, I knew too that the vegetation of North America differs from that of Europe and that there are only a few species common to both sides of the water. What will be the impression of the landscape—will it be European or a different type? But when I put my foot on the land near Quebec I became aware that the general features of the landscape and the surroundings of man were nearly the same there as in Europe, and only a closer inspection convinced me that I was amid a new flora. Indeed, I had the feeling of being not in a latitude south of Vienna, whence I had just come, but rather of being in the same surroundings as at Stockholm—twelve degrees of latitude farther north.

There are, indeed, very strong similarities between North America and Europe. A superficial glance at our maps will reveal similar features. Europe is only a peninsula of Asia, and the peninsular character determines all features of this continent. North America may be compared with the whole of Eurasia, and its eastern part shows a similar peninsular articulation as

¹MSS. intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

¹Inaugural lecture by the Kaiser Wilhelm Professor, delivered at Columbia University on November 3, 1908.

Europe. That peninsular region stretches east of the Mississippi Valley, the region of the Great Lakes and Hudson Bay, and there are doubtless more pronounced geographical differences between this articulated part and the continental part of North America than between peninsular North America and peninsular Eurasia—that is, Europe.

Europe gets its characteristic features from some invasions of the sea. Northeast of Scandinavia a part of the Arctic Sea penetrates into the land and branches here as the White Sea. Farther south the very edge of the continent seems to be inundated, so that Great Britain and Ireland are isolated, and from the German Sea the Baltic Sea extends far into the interior of the continent. Still farther south is the Mediterranean Sea, which separates Europe from Africa. All these features seem to be repeated on the west side of the Atlantic. Here we see the Arctic water penetrating far to the south, forming Hudson Bay. Farther south the eastern corner of North America is inundated; Newfoundland is isolated, like Great Britain; and the Gulf of St. Lawrence extends far into the interior of the country, getting its waters from that remarkable group of lakes which in many respects resemble the Baltic Sea. This resemblance was far stronger at the end of the last geological epoch, when a vast body of fresh water existed instead of the Baltic Sea which poured through the river valley of the Sund between Denmark and Sweden into the basin of the German Sea. The resemblance of the Gulf of Mexico to the Mediterranean is such a striking one that Alexander von Humboldt called it a mediterranean sea; and, indeed, it divides America into two separate continents—North America and South America.

These similarities between Europe and peninsular North America are not merely superficial ones. In a very remarkable

way, these two sides of the Atlantic repeat the same structural features; there is an astonishing symmetry, as Eduard Suess has shown so clearly. The northeast of Canada and Labrador on one side, and Scandinavia with Finland, the region of Feno-Scandia, on the other, are both composed of the oldest rocks we know of. These have a very complicated structure, being intruded with many eruptive rocks, and in a secondary way only, the surface features of the above regions are dependent on their structure. Both regions had already been leveled down before Cambrian times, and they sink gently down under a cover of horizontal Paleozoic strata. Both were called by Suess shields. The resemblance between these shields is the more conspicuous because both were covered during the last ice age by a glaciation which molded their surface in a similar way. In Sweden and Finland we find the same rounded glaciated surface, the same numerous lakes, as in Canada, both regions of the earth claiming to be the land of the many thousand lakes. At the border of both regions the horizontal Paleozoic strata begin with an escarpment which is pronouncedly developed south of Lake Erie and south of the Gulf of Finland, called here the “glint,” and we shall keep this expression to designate similar escarpments. These strata continue far into the interior of Eurasia, and they do the same in North America.

In the same way that we compare the Canadian Shield with the Scandinavian Shield we can compare the region east of the Mississippi Valley with the interior of Russia—both parts of the world have never been compressed by mountain-folding since Paleozoic time. Only a few faults occur here, and the whole geological history consists in slight up-and-down warps which brought both regions several times under the surface of the transgressing ocean. Also, here the younger geological history

has augmented the similarity. Huge morainic accumulations south of the Great Lake region of North America form the watershed between the Mississippi and St. Lawrence Rivers, and similar morainic deposits form the watershed between the Baltic and the Black Seas. Thick loess deposits are found in front of these morainic deposits in the Mississippi basin as well as in the interior of Russia. The loess gives rich harvests to the corn regions of Iowa, Nebraska, Kansas, Missouri and Illinois, the counterparts of which are found in Wolhynia and the region of the Tshernomom of the south central governments of Russia.

East of the Mississippi basin the old Paleozoic strata are folded and form the Appalachian belt, and similarly, west of the plains of Russia the Paleozoic strata of Europe are folded, forming a set of mountains which we can trace from the south of Russia to the west coast of Europe. In the central part of Germany these mountains constitute the belt of the German upland, and here it was that their geological history was first understood. The folding of the strata occurred near the end of the Paleozoic era and ceased before the end of the Permian epoch. Then they were base-leveled and covered totally or in part by Mesozoic deposits, after which mountains arose by faulting and warping, forming here and there true tilted blocks. The elevated parts lost their Mesozoic covering and the folded old strata again became visible.

This history is nearly the same as that of the Appalachian region. Here also the folding of the strata ended towards the close of the Paleozoic era and the folded mountains were leveled down. Then they became partly or totally covered with Mesozoic deposits, and the mountains of to-day were formed by upheaval. In North America, indeed, they form a more

connected zone, while in Europe they are mostly groups of mountains, separated from each other by basins of Mesozoic or younger strata. During the epoch of folding, the Appalachian region and the zone of the Hercynian Mountains of Europe may have formed mountains of the height of the Alps of to-day. I called them, therefore, the Paleozoic Alps of middle Germany, but to-day these regions have only lower altitudes; they do not surpass, as the Appalachian region does, 2,000 meters. The striking features of these base-leveled Paleozoic mountains consist of the fact that on both sides of the Atlantic the belt of their ancient foot-hills contains coal measures. As the Allegheny region in North America, so the mountains of South Wales, the northern boundary of the Ardennes and of the neighboring Rhenish mountains contain the richest coal measures. And as we find west of the Allegheny region some coal measures, so we find some extensive coal layers north of the belt of the Hercynian Mountains in England and Scotland, in upper Siberia, in the east of Germany, and in some places in the interior of Russia. The industrial evolution of eastern United States, of England and Wales, or Belgium and the German empire, is based on the same fact, that a rich vegetation once covered the foot-hill region of the mountains up-turned towards the end of the Paleozoic era.

It is very interesting to see how the Appalachian region ends at Newfoundland, forming the projecting eastern corner of North America, and just opposite in south Ireland, in South Wales, in Cornwall and in Brittany the belt of the old Hercynian Mountains of Europe begins. One seems to be the continuation of the other, and such an excellent geologist as Marcel Bertrand maintained that we have here to deal with the two ends of one very extensive belt of mountains which extended through

the North Atlantic Ocean. But we must not forget that the missing link between both ends of these supposed mountain chains is longer than their known extent.

There are also similar structural features between the Mediterranean Sea and the Gulf of Mexico and its surroundings. Both seas consist of a set of very deep basins, separated by higher regions which reach more or less above the sea-level, and the Mesozoic strata in their vicinity are folded, but there is one very marked geographical difference between their surroundings. On the north side of the Mediterranean Sea extends a nearly uninterrupted belt of mountains which contains the highest elevation of Europe, while there is no high mountain range at all at the north of the Gulf of Mexico. The high elevations on the north side of the Mediterranean sharply divide western Europe into an Atlantic and a Mediterranean part, while all the natural regions of eastern North America continue uninterrupted to the Gulf. The high mountain belt on the north side of the Mediterranean Sea prevents the rivers from entering the Mediterranean; it pushes aside the Danube and only the east annex of the Mediterranean—the Black Sea—receives in the Danube, the Dneiper and the Don, important rivers which can be compared with the branches of the Mississippi River. But the river of Europe which as to size and ramifications bears most resemblance to the Mississippi—the Volga—empties its waters into the Caspian Lake. This, the largest lake on the earth, can be regarded, however, as an isolated basin of the Mediterranean. During the Ice Age its waters stood probably so high that they could overflow through the Manytsh Valley, north of the Caucasus, into the Black Sea so that the Volga got an outlet into the open sea. Therefore, during the Ice Age the arrangement of the eastern European rivers corresponded more nearly

with that of the Mississippi and its branches, and this similarity would even exist if we assume that then the Black Sea itself was an inland sea, for such an inland sea could pour its waters through the Bosphorus into the Mediterranean. The Bosphorus, indeed, bears many features of a river valley, and it may have been at one time the outlet of all European rivers from the Danube to the Volga, of a body of water as large as that of the Mississippi. But while the large American river enters the sea through a large delta deposited by it, the European Mississippi passed through narrows just above its mouth, as the Hudson does; it had to force its way through the mountain belt north of the Mediterranean.

The absence of such a mountain belt in North America causes an important difference in the climate of the peninsular regions on both sides of the Atlantic. The climate of Europe is hardly at all affected by the Mediterranean, whereas the absence of a mountain belt north of the Gulf of Mexico allows the winds to sweep around the west end of that zone of high atmospheric pressure which extends across the Atlantic. Thus we have southwestern winds in North America; and as the southwestern winds of Europe bring the moisture and the warmth of the Gulf Stream drifts over large areas of Europe, so also the moisture and warmth of the Gulf of Mexico is brought into the southeastern part of North America. The effect of the cooling influences which the interior of a continent can exert by its high pressure and cold on the mean latitudes of its east coast, is counteracted to a large extent, and peninsular North America enjoys as well, but not as much, as the European peninsula of Eurasia, a peninsular climate.

But the peninsular climate of both sides of the Atlantic is not the same. It is most strongly developed in peninsular North

America in the south, but in Europe, in the north. The southwest winds blow in peninsular North America mostly during the summer; in Europe, however, during the winter, just at the time when cold northwest winds bring cold waves to the United States, and similar temperature is met with in very different latitudes of both sides of the Atlantic. Indeed, the climate on both sides of an ocean can not be the same; there must be differences between the east and west shores of the continents. Europe has the true climate of the west coast of a continent. The climate of this side of the Atlantic has its exact counterpart in North America in British Columbia, and the Mediterranean climate reoccurs in all of its characteristic features farther south in California. The high elevations of the mountains of British Columbia and of the Sierra Nevada, however, hinder the extension of these climatic conditions into the interior of the continent, while the open west of Europe allows the western winds to carry their moisture very far into the interior, and the long extent of the Mediterranean Sea is accompanied by a climate like that of California from the south of Spain over the south of Italy and Greece as far as Asia Minor. Thus one very large climatic province of very uniform character extends between the Atlantic Ocean and those semi-arid regions in which the higher civilization of the Orient in ancient times was born. And this climatic province possesses many features similar to those of semi-arid regions. This fact is of the greatest importance for the evolution of civilization in Europe.

We can trace back the European population very far. Man witnessed in Europe that set of climatic changes which characterize the great ice age, but while it is still open to discussion whether the present population of Europe had its origin in that

very old one or whether it came from Asia, there can be no doubt that the European civilization has its root in the Orient. Here in Mesopotamia and in Egypt an early civilization arose under arid and semi-arid conditions, based on irrigation; this civilization was brought by early navigators over the whole basin of the Mediterranean and it found congenial conditions everywhere along the shores. In America such an evolution was impossible. Indeed, an original civilization has grown up here under semi-arid conditions, and it was based, too, on irrigation. This is not surprising. Irrigation is the easiest way to introduce agriculture. It is only necessary to distribute water and crops become possible. There is not necessary the very difficult work of clearing the forests. But a certain political organization is necessary which begins at the moment when the rules are established according to which the water is distributed.

The conditions under which the early civilization on the plateau of Mexico was developed are, indeed, in many respects similar to those of the Orient. That civilization, however, was not only far more feeble than that of the Orient, but it could not extend in the same way. The American Mediterranean is far larger than that between Europe and Africa, and early navigation did not find here the same landmarks which allowed the Phoenicians and Greeks to sail so far, but above all the shores of that sea were not as inviting to settlers as those of Greece, Italy, Spain or northern Africa. They are covered for a wide extent by dense, tropical, nearly impenetrable forests, and a belt of those virgin forests hindered the Mexicans from extending their civilization down to the Gulf of Mexico. At no time has this sea played a rôle similar to the Mediterranean; a Roman empire could never grow up east of the cradle of the American civilization

along the shores of the sea between North and South America.

The Roman empire was a true Mediterranean state, but it pushed forward its frontiers as well to the deserts of the Orient as to the woodlands in the north. Woodlands only rarely favor the evolution of a primitive civilization. Agriculture needs here more than irrigation; the forests must be cleared. This is a very hard work which goes on very slowly, and it must be followed by a continual struggle against the constantly new-growing forests. Here the family work has the greatest success and political organization only will very likely be formed. Indeed, the Romans regarded the wood-folk in the north as barbarians, though these had a civilization of their own which was of not inconsiderable height. They had already submitted extensive ground to agriculture; they already manufactured iron, and they were settled in villages and towns. But there can be no doubt that the Romans brought them more of the high civilization of the Orient than had reached them through the commerce of the Phœnicians and Greeks. By this, the Romans aided their neighbors in the north until finally the latter left their forests and conquered the south.

This political movement had as a starting-point central Europe. This is the center around which the other parts of Europe are arranged in such a way that they can be directly reached, and while most of these other parts are more or less separated from one another, lying isolated like Great Britain, or stretching into neighboring seas like Scandinavia, or Spain, or Italy, or the Balkan peninsula, they all are either connected with or are near to central Europe. Therefore, the relations between those members of Europe and the center were always active. Open to all sides, this center has suffered by its neighbors when its population was feeble and without

force; or, on the other hand, when its inhabitants are strong, they influenced all Europe. More than once central Europe acted as the heart of the European body and drove fresh blood into the members.

When the forest-folk of central Europe had gained from the Romans knowledge of the favored regions of the Mediterranean basin rich in all kinds of fruit, they began to move towards the south; they laid in ruins the Roman empire and founded new kingdoms, but they could keep their nationality only where they appeared in great numbers. They were absorbed by the peoples of southern Europe, and the German ground extended only in the southwest, along the Rhine, and in England. England still bears the name of the German tribe—the Angles—who, together with the Saxons, conquered that extreme part of the old Roman empire, and in the whole of Europe we find witnesses of former German immigration. In the south of Spain, the name of Andalusia reminds us of the German tribe of the Vandals who came from the Baltic Sea. In upper Italy, Lombardy conserves the name of those long-bearded Germans who settled there, and in the regions north of Milan you see more blond people with blue eyes than in many parts of the German empire. France received her name from the German Franks who extended their empire there.

The emigration of the German wood-folk seems not to have been caused by the pressure of other peoples. There seems to have been awakened a yearning among the German tribes to occupy better countries than their own. It seems to have been a similar longing to migrate and to settle new countries as that which prevailed in the eastern states of North America for more than one hundred years and which caused that enormous extent of the Anglo-Saxon race over the whole continent of North America. As in New England, the woodlands which were

left by their agricultural population were settled by new emigrants—the old Puritan ground being entered by Roman Catholic Irish and Italians and French Canadians and Russian Jews—so also in Germany the areas were resettled which had been left by their emigrating inhabitants, especially the eastern part. But the emigration had been more complete than in eastern New England, and the new settlers found a vacant country in which they could introduce their own language. A reaction, however, set in, and since the times of Charlemagne the Germans have been taking back their old land from a population whose descendants are to-day, in North America, classed as undesirable immigrants.

While this was beginning, the northern neighbors of the Germans, the Scandinavians, were seized with a similar longing to migrate that the Germans had experienced several hundred years ago, but while the Germans migrated on the land, the Scandinavians went on the sea. Scandinavian tribes crossed the Baltic Sea and crossed into the forests of northern Russia, where they founded the Russian empire, the name of which points back to the times when the Scandinavian conquerors used their slavish subjects as "rowmen." Scandinavian pirates devastated the coast of northern Germany, of England, Scotland and France, where they settled, forming Normandy. They sailed into the Mediterranean Sea and at Constantinople met with countrymen going through Russia. Others went into the northern seas, discovering the Fæer Oer, Iceland and Greenland. They even came over to North America, but this discovery was accompanied by a large number of men prepared to settle, and it remained unknown to the greater part of Europe. Even Greenland was totally forgotten, and its few Scandinavian inhabitants expired when they came into contact with the Eskimo population. Thus

the outburst of Scandinavian peoples, like the older outbursts of German peoples, resulted in but a slight expansion of Scandinavian ground. The Norman settlers along the Mediterranean and the shores of the Channel became intermixed with their neighbors, and when the Normans conquered England they brought with them French language and French customs.

In Germany, after the time of martial expansion of the people was over, more settled conditions ensued, and the vast forest-clad mountain regions which had heretofore been only visited by hunters were now cleared and a kind of interior colonization took place in the central part of the empire. The terminations "*reute*" and "*schwende*" of names of German villages indicate that the clearing of their forests was either by felling or burning the tree, and so famous became the Germans as clearers of woodland that they were called into the mountains of Bohemia, Silesia and Hungary, where peaceful colonization took place. German colonies, following the extension of German sea traffic, were founded along the shores of the Baltic Sea and even on the west coast of Norway, where the city of Bergen is a German colony; even centuries after, when the Russian empire had been extended from the Baltic to the Black Sea and to the Pacific, Germans were invited to settle in order to cultivate the country. These German colonies, which spread over all Russia, are found even in the steppe countries east of the Volga and of the Crimea.

Those waves of Asiatic steppe roughriders which now and then spread out over the low ground of eastern Europe, were always broken when they reached German ground. Here the Hungarians were defeated. The Mongolian wave which had terminated the early Russian empire met with the same fate when it came to eastern Germany, as did the wave of Turks which

so easily rushed over Hungary. From the walls of Vienna imperial German armies drove back the Turks into those frontiers of Turkey, which lasted until the end of the nineteenth century, and German settlers founded a new culture in Hungary.

Thus the influence of early German conquest and later German peaceful colonization is felt nearly over the whole of Europe. The earlier conquest formed the nobility of France and Italy, where many noble families still conserve more or less corrupt German family names, and German names were long in use for noblemen in medieval times. German colonists developed the agricultural resources of the southeast and east of Europe and German merchants extended their commerce on the coast of the whole Atlantic Europe.

This kind of peaceful German extension is also favored by the central position of Germany in Europe, but it is very much based on the fact that Germany herself is not a country too much favored by nature, and it is her very poor soil which has educated her population to strong and intelligent labor. This population, however, increased to greater numbers than the ground could support, and this is the real cause of the expansion of German population by immigration, the influence of which has been so markedly felt by all Europe. It is the natural expansion of a strong, working forest-folk and one which resembles very much the expansion of the people on the east coast of North America over a whole continent.

The virgin forests of peninsular North America were far out of the reach of original American civilization, which could neither spread out over the shores of the American Mediterranean nor cross the arid regions and deserts north of Mexico. Their Indian inhabitants remained in the state of hunters and never cleared the woodland. The natural riches of that region were de-

veloped only when it was settled by Europeans, who had learned in Europe to overcome the resistance of forests to agriculture. And soon after its colonization, its population experienced that strong wish to expand which is so characteristic of early German migrations. The descendants of that population on the Atlantic slope of North America, who had cleared the virgin forests, crossed the Appalachian chain, cultivated the prairie grounds of the Mississippi basin, and adapted themselves to the arid climate of the west and the Italian climate of California. Thus the Atlantic side of North America plays in its colonization a rôle similar to that of Germany in the history of Europe.

The expansion of eastern North Americans, however, met with no strong resistance from the other inhabitants of North America. The Indians defended their ground in insufficient numbers and with insufficient arms, and they died out when they came into contact with higher civilization. In Europe, on the other hand, German emigrants spread amid peoples of larger numbers, and became, therefore, partly absorbed. The difference in expansion between the Atlantic North American and the German populations is neither caused by a greater strength of the North American expansion, nor by a lower education of German settlers; it is due to the fact that the North American expansion extended over a continent inhabited only by nomadic tribes of small numbers and of low civilization, while the German expansion extended over vast areas occupied by peoples with a culture and an organization of their own. This again is due to the fact that higher civilization spread out over all Europe, while the native civilization of North America remained restricted to the plateaus west of the Gulf of Mexico.

There is a remarkable resemblance between the expansion of German population

and that of America, and if we follow the latter to its sources we find that the early English settlers on the east coast are the descendants of German conquerors of England and their extension towards the west was followed and reinforced by a powerful wave of peaceful German immigrants, differing in language but similar in kind, and both waves formed one population in which the old German spirit of expansion is very active.

It is a curious chance that America received its name from a German geographer. Old Professor Waldseemüller made a mistake, indeed, when he named the new countries at Brazil after the Florentine Amerigo Vespucci. It would have been far more just to name the new world after Columbus, but though Waldseemüller recognized his mistake and withdrew the name, it remained in use. And curiously enough, that Amerigo Vespucci whose name gave origin to the name of America, had himself, though an Italian, still a German family name, Emmerich, Emery in English. Thus America is a continent with a German name, the meaning of which might, perhaps, be interpreted as "rich in corn";² if this is correct, Professor Waldseemüller chose an incorrect but appropriate name.

There are many connecting links between North America and Germany, but the strongest of these links is mutual friendship. True friendship needs no long words. I say to my friend, "Come, enter my house and feel at home"; and so I invite you to enter my home with me and to listen to my lectures on Germany.

ALBRECHT F. K. PENCK

REPORT OF THE COMMISSION ON AGRICULTURAL RESEARCH

THE Commission appointed by the Association of American Agricultural Colleges and Experiment Stations in 1906, to consider

² *Amar*, old German, a kind of wheat.

the organization and policy that should prevail in the expenditure of public funds for agricultural research, and kindred matters, has presented its report.

The members of the commission, David Starr Jordan, Stanford University, California, chairman; Whitman Howard Jordan, of Geneva, New York, secretary; Henry Prentiss Armsby, State College, Pennsylvania; Gifford Pinchot, Washington, D. C., and Carroll Davidson Wright, Clark College, Worcester, Massachusetts, agree in signing the report except that Mr. Pinchot makes some reservations. They summarize their recommendations as follows:

1. Every effort should be made to promote the training of competent investigators in agriculture both in the agricultural, and, so far as practicable, in the non-agricultural, colleges and universities, and their training should be as broad and severe as for any other field of research.

2. The progress of agricultural knowledge now demands that agricultural research agencies shall deal as largely as possible with fundamental problems, confining attention to such as can be adequately studied with the means available.

3. The work of research in agriculture should be differentiated as fully as practicable, both in the form of organization and in the relations of the individual investigator, from executive work, routine teaching, promotion and propaganda, and should be under the immediate direction of an executive trained in the methods of science who should not be hampered by other duties of an entirely unlike character.

4. The investigator should be free from all coercion whatever. In reaching his conclusions he should be equally free from the prescription of received opinion and the temptation to exploit his results for the purpose of obtaining future support. To this end, his work should be as far removed from immediate dependence upon legislation as is consistent with due responsibility to the public, and his relations to the public and to the organization of which he is a member should be such as to promote individual initiative and not interfere with freedom of conclusion or utterance on scientific questions.

5. There should be a clearer definition of the relative fields of work of the United States Department of Agriculture and the experiment stations. The dominance of the stations within their

respective fields should be preserved and their growth fostered, as agencies for the investigation of local questions and of the more individual scientific problems. The federal agency, on the other hand, should cultivate the almost limitless field offered by questions having national or interstate relations and by those broad scientific problems requiring heavy expenditures, elaborate equipment, long continued study and the correlation of the results of many investigators, which efforts are usually beyond the means of an individual station. On many questions the harmonious cooperation of the two agencies is essential to the highest efficiency of effort.

6. Any research agency charged with a single main line of investigation should be so organized that it may employ within itself all necessary processes in any branch of science. The cooperation of any or all the departments of an experiment station on a single problem, when necessary, should be a fundamental requirement.

7. Research work, both national and state, should be provided for by separate, lump-sum appropriations, to be distributed according to the discretion of the responsible executive head of each agency.

8. Investigation into the business, economic, social and governmental conditions affecting agriculture should be undertaken and should be maintained on a permanent and effective basis.

9. An advisory board is suggested consisting of members appointed by the Secretary of Agriculture and by the Association of American Agricultural Colleges and Experiment Stations, respectively, which shall confer with the Secretary of Agriculture regarding the mutual interests of the department and the stations and shall consider the promotion of agricultural investigation in general.

THE RHODES SCHOLARSHIPS

THE number of scholars in residence at Oxford under the Rhodes bequest during the academic year 1907-8 was 156. Sixty-six were from colonies of the empire, 11 from Germany and 79 from the United States of America. In addition to these, 11 men whose scholarship term had expired continued to reside in the university for a whole or part of the year; 1 as an official fellow, 2 as lecturers, 1 as a Senior Demy of Magdalen and 6 for further study in various subjects. At the end of the summer term 54 scholars completed

their course at the university and took their examinations. At the beginning of the October term 1908 there was an entry of 78 new scholars, while 3 other scholars (colonial) who had temporary leave of absence returned to complete their course. The whole number of scholars in residence for the academic year 1908-9 is therefore 178. These are distributed as follows among the colleges: 15 at Balliol, 14 at Christ Church, 13 each at Exeter and Queens, 12 at St. John's, 11 each at Hertford, New College and Worcester, 10 each at Merton and Wadham, 9 at Oriel, 8 each at Lincoln and Pembroke, 7 each at Brasenose, Trinity and University, 6 at Magdalen, 4 at Jesus and 2 at Corpus. There are, in addition, 11 ex-scholars in residence for the October term, engaged either in teaching, research or special study for examination. The total so reached of 189 is the highest point in numbers hitherto attained. The work of the scholars now in residence is distributed as follows over the different courses of study organized in the university: Literæ Humaniores, 20; natural science (geology, chemistry, physiology and physics), 18; jurisprudence, 38; history, 20; mathematics, 4; theology, 9; English literature, 7; oriental languages, 1; modern languages, 4; Honor Moderations—classical, 3.

THE DARWIN CENTENARY

IN addition to the exercises in New York, Philadelphia, Chicago and elsewhere in honor of the hundredth anniversary of Darwin's birth, which have already been noted in *SCIENCE*, memorial exercises were arranged by several other institutions.

At Cornell University the event was commemorated by two lectures by Professor J. H. Comstock on "The Basis of the Theory of Evolution," a lecture on "The Relation of Darwinism to the Modern Theories of Evolution," by Professor Herbert J. Weber, and an address by President Schurman on "Darwinism and Modern Thought."

At a special meeting of the Scientific Association of the University of Missouri, held on February 12, in commemoration of the

one hundredth anniversary of Darwin's birth and the fiftieth anniversary of the publication of the "Origin of Species," the following addresses were delivered: "Biographical Sketch of Darwin," by Professor W. C. Curtis; "Darwin's Contribution to Evolution," by Professor C. Stuart Gager; "Pre-Darwinian Evolution," by Professor A. O. Lovejoy; "Post-Darwinian Evolution," by Professor George Lefevre; "The Influence of Darwin's Work on Ethics," by President A. Ross Hill; "The Influence of Darwin's Work on Sociology," by Professor C. A. Ellwood; "The Influence of Darwin's Work on Psychology," by Professor Max Meyer; "The Influence of Darwin's Work on Theology," by Rev. Dr. W. W. Elwang. Mr. F. A. Sampson, secretary of the State Historical Society of Missouri, read a most interesting series of letters written by Darwin about 1878 to Mr. R. A. Blair, of Sedalia, Missouri, concerning what was at first supposed to be a case of the inheritance of a mutilation in a flock of geese.

On Thursday evening, February 11, Dr. J. M. Reade, of the University of Georgia, delivered a lecture on "Charles Darwin," before the University Club. Commemoration exercises were held at the home of Professor H. C. White, of the University of Georgia, on Friday, Feb. 12, in honor of Darwin. The program consisted of: "Biographical Sketch," by Dr. H. C. White; "Organic Evolution," by Dr. J. P. Campbell; "Evolution in History," by Dr. J. H. T. McPherson; "The Church and Evolution," by Rev. Troy Beatty.

A SPECIAL meeting of the Boston Society of Natural History was held on the evening of February 12, in commemoration of the centenary of Charles Darwin's birth and of the fiftieth anniversary of the publication of his "Origin of Species." After introductory remarks by Vice-president R. T. Jackson, the following brief addresses were made: By Professor W. H. Niles on the "Early Life of Darwin and his Contributions to Geology"; by Professor E. S. Morse on "The Factors of Darwinism"; by Professor G. H. Parker on "A Mechanism for Correlated Characters," and by Professor W. M. Wheeler on "Pre-Darwinian and Post-Darwinian Biology."

At the general meeting of the American Philosophical Society on the evening of Friday, April 23, a Darwin celebration will be held. Charles Darwin and his grandfather, Erasmus Darwin, were members of the society, and his son, Sir George Darwin, is at present a member. On this occasion there will be three special addresses by members of the society: The first by the Right Hon. James Bryce, the British ambassador, who will give some personal reminiscences of Darwin and of the impression made by the appearance of the "Origin of Species" in 1859; the second by Professor Goodale, of Harvard University, on "The Influence of Darwin on the Natural Sciences," and the third by Professor James Mark Baldwin, of Johns Hopkins University, on "The Influence of Darwin on the Mental and Moral Sciences."

SCIENTIFIC NOTES AND NEWS

PROFESSOR CHARLES B. RICHARDS, professor of mechanical engineering at Yale University since 1884, and Dr. W. G. Sumner, professor of political and social science since 1872, will retire from active service at the close of the present academic year.

THE Rumford Committee of the American Academy of Arts and Sciences has recently made the following grants: To Director W. W. Campbell, of the Lick Observatory, \$250, for the purchase of a Hartmann photometer; to Professor R. W. Wood, of the Johns Hopkins University, \$150, in aid of his research on the optical properties of mercury vapor.

MR. O. J. R. HOWARTH has been appointed assistant secretary of the British Association in succession to Mr. A. Silva White.

SIR DANIEL MORRIS, K.C.M.G., late British commissioner of agriculture for the West Indies, has been selected for the newly-created office of scientific adviser to the secretary of state for the colonies on matters relating to tropical agriculture.

DR. R. PILGER has been appointed custodian of the Botanical Garden in Dahlem, Berlin.

THE committee of the Athenaeum Club has elected, under the provisions which empowers the annual election by the committee of nine

persons "of distinguished eminence in science, literature, the arts, or for public services," Mr. Horace T. Brown, F.R.S., LL.D., and Sir David Bruce, F.R.S.

SIR WILLIAM WHITE was the guest of the Sheffield Society of Engineers and Metallurgists at their biennial dinner on February 26.

DR. F. A. DIXEY has been elected president of the Entomological Society of London.

PROFESSOR RAMÓN Y CAJAL, of Madrid, and Professor Emil Fischer, of Berlin, have been elected honorary members of the Paris Biological Society.

A SWISS Neurological Society has been formed, the headquarters of which are at Zürich and the first president of which is Professor von Monakow.

We learn from *Nature* that Dr. F. H. Hatch has been appointed by the government of Natal to make an examination of the mineral resources of the colony, and will shortly proceed to South Africa for that purpose.

DR. SVEN HEDIN lectured before the Royal Geographical Society on February 7, and proposed to give a number of lectures in England in the course of the following month on "My Recent Expedition in Tibet."

CONVOCAATION DAY was observed by the University of Pittsburgh on February 12, Lincoln's birthday. An address was made by Colonel Samuel Harden Church upon Lincoln, by Dr. W. J. Holland upon Darwin, and by Dr. J. A. Holmes, of the United States Geological Survey, upon "The Conservation of Our National Resources." Vice-president-elect James S. Sherman was present and made a brief address. The honorary degree of LL.D. was conferred upon Hon. James S. Sherman, Colonel S. H. Church and Judge William Waugh, of Greenville, Ohio, who graduated from the university seventy years ago in the class of 1839. The degree of Sc.D. was conferred upon Mr. F. A. Lucas, curator-in-chief of the Brooklyn Institute of Arts and Sciences, Dr. J. A. Holmes, of the United States Geological Survey, and Mr. Edward Goodrich Acheson, the electrical engineer.

A SUM of over \$10,000 has been subscribed to a monument to be erected in honor of Berthelot, the eminent chemist.

DR. CARROLL D. WRIGHT, the first president of Clark College, U. S. Commissioner of Labor from 1885 to 1905, president of the American Association for the Advancement of Science in 1904, eminent for his contributions to statistics and sociology, died at Worcester, Mass., on February 20, at the age of sixty-eight years.

DR. ERNEST S. WHEELER, lecturer on tropical medicine in the Dartmouth College Medical School, died on February 15, at the age of forty years.

At the suggestion of the North American Conference on the Conservation of Natural Resources, in session in Washington last week, President Roosevelt has determined to issue, through the state department, invitations to all nations to send delegates to an international conference on conservation, to be held at The Hague.

MR. ANDREW CARNEGIE has given \$100,000 for branch buildings to the Cincinnati public library.

DR. GEORGE GORE, F.R.S., formerly lecturer on chemical and physical science at King Edward's School, Birmingham, who died on December 20, aged eighty-two years, left an estate valued at £6,802. The testator left £500 in personal bequests and £100 to the Birmingham University. All his other property he left equally between the Royal Society and the Royal Institution of Great Britain.

THE Gordon Wigan income for 1908 at the disposal of the Special Board of Biology and Geology, of Cambridge University, has been applied as follows: (a) £50 to D. Sharp, M.A., the curator in zoology; (b) £50 to A. G. Tansley, M.A., to enable the Botanic Garden Syndicate to continue to offer special facilities for plant-breeding experiments; (c) £50 to Professor Hughes, being £30 for the purchase of a projection lantern for the geological department and £20 for the expenses of research on Pleistocene deposits in the neighborhood. The prize of £50 from the fund for

an investigation in chemistry was awarded to Leonard Angelo Levy, B.A., Clare, for his essay entitled "Investigations on the fluorescence of Platinocyanides." Grants out of the balance on income account amounting to £180 were made to the departments of physics, mineralogy and engineering, to defray the cost of special apparatus.

By arrangement with the Bermuda Natural History Society, the Station for Research at Agar's Island will be open for about seven weeks this summer. There are accommodations for a limited number of instructors or research students in either zoology or botany. Members of the expedition will sail from New York on one of the steamers of the Quebec Steamship Company's Line (probably the *Bermudian*) about the middle of June, or, for those who can not sail so early, about the first of July. Further information may be obtained from Professor E. L. Mark, 109 Irving Street, Cambridge, Mass.

A PLAN of cooperation between the United States Bureau of Plant Industry and the department of pharmacy of the University of Wisconsin has been adopted, the purpose of which is to provide for the cultivation of medicinal plants. Investigation and research work is to be carried on in connection with the growing of those plants used in the preparation of drugs and medicines.

A TUBERCULOSIS exhibit consisting of the Wisconsin exhibition at the International Tuberculosis Congress, together with reproductions of the best features of all the other exhibits at that congress, has been prepared by the department of bacteriology of the University of Wisconsin and the Wisconsin Anti-Tuberculosis Association, and is to be sent out to cities throughout the state by the university extension division of the state university. The exhibit shows in graphic and striking forms the great losses resulting from the ravages of tuberculosis, the best preventive measures and the most effective and economical means of cure. An experienced demonstrator will be in charge of the exhibit

to explain the various charts, doors of houses, sleeping bags, window tents, photographs, etc.

DR. J. O. WAKELIN BARRETT and Dr. Warrington Yorke, members of the Blackwater fever expedition of the Liverpool School of Tropical Medicine, who went out to Nyasaland in August, 1907, have returned. The *London Times* states that the expedition was well provided and equipped for pathological and chemical research, and during their fourteen months' operations the investigators had unusual opportunities for studying the fever. According to their report, nearly all the cases occurring in the protectorate came under their observation. Every assistance was afforded the expedition by the government medical staff and the Shire Highlands Railway Company, the latter granting special facilities for the use of the line, which was a matter of great importance, seeing that the majority of attacks of blackwater fever occurred in the vicinity of the railway. The fever, however, is usually most prevalent during the rainy season, when means of communication are more or less interrupted, and movement from place to place is difficult. Hence the members of the expedition sometimes had to travel in extremely heavy rain, but even that was found preferable to the intense heat of the midday sun by the river. The expedition, the cost of which was met equally by the Colonial Office and the Liverpool School of Tropical Medicine, was from time to time in touch with the expedition sent out by the school nearly two years ago for the study of sleeping sickness in northeast Rhodesia and the south of Lake Tanganyika. The school has also a yellow fever expedition in Brazil and a malaria expedition in Jamaica.

THE Belgian Permanent Committee on Human Alimentation, which was founded on the occasion of the International Congress on Food held at Ghent in 1908, held, as we learn from the *British Medical Journal*, its first meeting at Brussels on December 28, 1908, under the presidency of Dr. A. J. J. VanderVelde, of Ghent. Among the objects aimed at by the committee are the organization in Belgium of congresses on food, and the par-

ticipation of that country in international congresses on the same subject, the study of questions relating to the prevention of fraud, the supervision of the sale and manufacture of food preparations, and the promotion of uniform international methods of analysis. The committee will also investigate the question of human food from the chemical, physiological, technical, commercial, legislative, economic and social points of view. The committee consists of fifty members representing the scientific as well as the industrial and commercial worlds. There are three vice-presidents: MM. Libotte, of Antwerp; Sohier, of Liège, and Professor van Laer, of Brussels. Dr. Schoofs, of Liège, is general secretary.

A FRIEND of the *Scientific American*, who desires to remain unknown, has paid into the hands of the publishers the sum of \$500, which is to be awarded as a prize for the best popular explanation of the Fourth Dimension, the object being to set forth in an essay the meaning of the term so that the ordinary lay reader can understand it. No essay must be longer than 2,500 words. Each essay must be typewritten, bearing only the pseudonym. With the essay should be sent a second plain sealed envelope, also labeled with the pseudonym and be sent to "Fourth Dimension Editor, *Scientific American*, 361 Broadway, New York, N. Y.," by April 1, 1909. Professor Henry B. Manning, of Brown University, and Professor S. A. Mitchell, of Columbia University, will be the judges.

ACCORDING to a special press bulletin prepared by Waldemar Lindgren, of the U. S. Geological Survey, the gold-mining industry of the United States had a prosperous year in 1908, in spite of adverse conditions of trade and finance. The director of the mint estimates the production of gold for 1908 from domestic sources at \$96,313,256, against \$90,435,700 in 1907. South Dakota, Alaska, California and Colorado show large estimated increases, ranging from \$2,000,000 to \$3,600,000. The estimates for Utah indicate a decrease of about \$1,200,000; for Nevada a decrease of \$3,300,000. The production of Montana, Arizona, Idaho, Oregon and other silver-producing

states has remained approximately stationary. The production from the Philippine Islands shows an increase, the estimate of the mint being \$306,708, against \$78,700 in 1907. As part of the Philippine gold does not reach the United States mints the showing is probably even better than these figures would indicate. Most of the gold was recovered by quartz mining in Benguet and by dredging operations in Paracale. The silver-mining industry presents a far less satisfactory condition than that of gold, owing to the low prices for silver, lead, copper and zinc. During the year the large smelters of Utah and Colorado were partly closed and partly operated on a reduced capacity.

THE following lectures will be delivered at Columbia University on The Henry Bergh Foundation for the Promotion of Humane Education, 1908-9, Wednesdays at 4.10 P.M., in Room 309 Havemeyer Hall:

February 3—"The Influence of Humane Ideals and Practises in Human Civilization," by Franklin Henry Giddings, Ph.D., LL.D., professor of sociology and the history of civilization, Columbia University.

February 10—"Pure Food as an Element in the Humane Treatment of Men and Animals," by H. H. Wiley, Ph.D., of the Department of Agriculture, Washington, D. C.

February 17—"The Humane Treatment of Animals," by Albert Leffingwell, M.D., of Aurora, N. Y.

February 24—"Science and Animal Experimentation," by Nathan Oppenheim, M.D., of New York.

March 10—"Hunting with the Camera," by George Shiras, 3d, of Washington, D. C.

March 17—"The Humane Treatment of Children," by Homer Folks, secretary of the New York State Charities Aid Association.

March 24—"The Humane Treatment of Criminals," by Samuel J. Barrows, D.D., president of the International Prison Commission.

March 31—"The Ethics of Punishment," by John Dewey, Ph.D., LL.D., professor of philosophy in Columbia University.

April 7—"The Economic Aspect of the Humane Treatment of Children and Animals," by Roswell C. McCrea, Ph.D., of the New York School of Philanthropy.

PROFESSORS MORTON PRINCE and George V. N. Dearborn, at the Tufts College Medical School, Boston, offer a course on psychopathology, required for fourth-year students of medicine. The course, which is said to be the first of the kind, will cover the following topics:

Mental physiology.—Mechanism of memory, including physiological (unconscious) memories (spinal cord and ganglia). Meaning of the unconscious. Formation and conservation of unconscious complexes. Meaning of the subconscious and co-conscious. Integrative action of the nervous system. Habit-formation. Emotion. Influence of psychical processes on the functions of the viscera (digestive, vasomotor, secretory, respiratory systems, etc.). Cenesesthesia. Hypnosis (theory and phenomena). Suggestion. Idea-complexes.

Dissociations of the mind.—Anesthesia. Paralysis. Amnesia. Abstraction. Hypnoidal states. Sleep. Trance states. Fatigue. Subconscious ideas and their activity. Unconscious processes. Abulia.

Syntheses.—Sensory automatisms (visual and auditory hallucinations). Paresthesia. Pain. Motor automatisms (spasms, contractures). Recurrent mental states. Obsessions. Impulsions. Fixed ideas. Delusions. Unconscious mental complexes and their influences. Dreams.

Special pathology.—Neurasthenia. Hysteria. Psychasthenia. Hypochondriasis. Phobias. Habit psychoses and neuroses. Mimicry. Psycholeptic attacks. Recurrent sensorimotor attacks. Amnesic states. Dissociated personality. Fugues. Tics.

Methods of examinations besides the ordinary clinical methods.—Psycho-analysis. Abstraction. Hypnoidization. Hypnosis. Automatic writing. Artificial hallucinations. Psychogalvanic tests. Word reaction tests.

Principles of psychotherapeutics based on psychopathology.

UNIVERSITY AND EDUCATIONAL NEWS

THE University of Virginia has completed an endowment fund of \$1,000,000 of which half has been given by Mr. Andrew Carnegie.

THE educational commission which has for the past two years been codifying and revising the school laws of Pennsylvania, has created Colleges of Education at the Universities of Pennsylvania and Pittsburgh. These colleges

will have as their specific functions the training of high school and normal school teachers, principals and superintendents of schools, supervisors of the various school grades, supervisors of special branches, and experts for service in the public school system of the Commonwealth. The code provides that the state shall pay the tuition of Pennsylvanians who are normal school graduates or who have successfully completed the sophomore year of a college. While no state aid is asked at the present session, it is provided that the legislature may make special appropriations for buildings, equipment and other needs of the Colleges of Education as from time to time may be deemed necessary.

IN accordance with the principles of university nomenclature adopted by the Association of American Universities, the University of Wisconsin has changed the title of the college of law to that of "Law School," and the name of the college of medicine was changed to that of "Medical School"; the recommendation of the Association of Universities being that the term "school" be applied to those professional departments requiring for admission at least two years of college work.

ON February 15 the University of Nebraska celebrated the fortieth anniversary of the granting of the charter under which the institution was organized. The address was given by Dr. Ellery W. Davis, dean of the College of Literature, Science and the Arts, on "A Coming Aristocracy."

THE scheme prepared by the charity commission under the will of the late Mr. John Innes, of Merton, has now been settled. The most important part relates to the institution of a national horticultural college at Merton.

THE Italian minister of education, Signor Rava, has pledged himself to the restoration in its integrity of the University of Messina, promising the students that it shall not be transferred elsewhere. Attention has been called to the fact that in view of the 16 other state universities, of which two are in Sicily—at Palermo and Catania—this concession to passing sentiment is to be deplored as only adding needlessly to the complications of the revival of Messina.

DR. JAMES BURRELL ANGELL submitted his resignation of the presidency of the University of Michigan on February 17, to take effect at the close of the academic year, and the board of regents created the office of chancellor and offered it to him at a salary of \$4,000 a year with the continued use of the president's house. Dr. Angell, who on January 7 last celebrated his eightieth birthday, has been head of the university since 1871, when he came from the presidency of the University of Vermont.

THE methods by which even our best daily papers are edited are illustrated by the fact that the *New York Sun*, on February 18, contained an article, the headlines of which announced that the presidency of the University of Michigan had been offered to Professor Jenks, of Cornell University, whereas in the article itself it was stated that no selection had been made. The *New York Times*, of February 20, contained an editorial article congratulating Professor Finley on his call to the presidency of the University of Michigan, and expressing hope that he would not go, especially on account of his admirable after-dinner speeches, whereas the news columns contained the statement that President Finley had denied that such a call had been made.

It is announced that Miss Agnes Irwin will resign the deanship of Radcliffe College at the close of the present academic year.

At Yale University, Professor L. P. Breckinridge, of the University of Illinois, has been appointed professor of mechanical engineering and Dr. W. R. Coe has been promoted to a full professorship of biology.

THE council of New York University announces the appointment of J. Edmund Woodman as professor of geology and director of the geological museum, to fill the vacancy caused by the retirement of Professor John J. Stevenson; and of Holmes Condict Jackson to be professor of physiology and director of the laboratory of physiology in the University and Bellevue Hospital Medical College, to fill the vacancy caused by the resignation of Pro-

fessor Graham Lusk. Professor Woodman received the degree of doctor of science from Harvard in 1904 and is now professor of geology at Dalhousie University, Halifax, Canada. Professor Jackson received the degree of doctor of philosophy from Yale University in 1899, and was instructor in physiological chemistry in the Sheffield Scientific School for three years. After study abroad he received an appointment as instructor in physiological chemistry in New York University, and became assistant professor in 1903. In 1905 he resigned to accept a position as adjunct professor in experimental physiology and physiological chemistry and director of the laboratories in the Albany Medical College, which position he now holds.

R. H. WHITBECK, of Adelphi College, Trenton, N. J., has been appointed associate professor of geography and physiography at the University of Wisconsin, beginning with the next academic year.

SIR T. H. HOLLAND, F.R.S., director of the Geological Survey of India, has accepted the offer of the chair of geology at Manchester University vacated by Professor Boyd Dawkins, F.R.S. Dr. W. H. Lang has been appointed Barker professor in cryptogamic botany and Dr. Marie O. Stopes special lecturer in palaeobotany.

DISCUSSION AND CORRESPONDENCE

APPOINTMENTS IN COLLEGES AND UNIVERSITIES

TO THE EDITOR OF SCIENCE: It has for several years been a question of absorbing interest to me whether our American methods of making university appointments might not be much improved, especially in view of the fact that much better methods are in operation in other countries. It was a pleasant surprise to me to notice that others were agitating the same question, as is made evident by the discussion begun by Professor Wenley and continued by Professor Miller in *SCIENCE* of August 21 and October 23, respectively. It seemed to me that the time was ripe for some action on this matter. I therefore seized the opportunity of presenting my views

to my colleagues of the Chicago Section of the American Mathematical Society, assembled in an informal way at a dinner on January 1, in connection with the regular meeting of that body. I enclose a copy of the remarks which I made upon that occasion. Let me supplement these remarks with the statement that a committee of the Chicago Section has been appointed to investigate the matter more closely and to report at the next meeting. The committee consists of Messrs. T. F. Holgate (Northwestern), E. B. Van Vleck (Wisconsin), L. E. Dickson (Chicago), A. G. Hall (Michigan) and E. J. Wilczynski (Illinois).

Mr. Toastmaster and Gentlemen: It is a difficult task which I have to fulfill to-night, to hold your attention after a hard day's work of mathematical deliberation, at a time when the average man seeks repose in friendly conversation. But I shall not attempt to excuse myself, and hope that you will pardon this rather unusual proceeding on account of the interest and the importance of the subject.

We have come together as mathematicians, but most of us are at the same time men in academic life and as such are naturally eager to examine our existing institutions, to inquire whether they are the best conceivable under the circumstances, and if not, to attempt to improve them.

I doubt whether it is necessary for me to spend much time upon an attempt to convince you that all is not as it should be in our American methods of university appointments. We all know of cases where these methods have failed to accomplish the best results, namely, to secure the best man available at a given time for a position then open.

Many of our universities and colleges make honest efforts to solve this problem for themselves, and would probably welcome any movement which would assist them in its solution. Others are indifferent, while still others almost openly practise favoritism of the rankest kind. Many of our smaller institutions rely to a considerable extent upon recommendations made by larger and more influential universities, and the latter have a tendency, quite pardonable under our system, of recommending only their own graduates. Again many of these same universities in filling vacancies in their own staff, never would consider a candidate unless he had been one of their own students. The question of personal acquaintance counts too much; whether a man is a good fellow,

or a man of conservative political and religious beliefs, whether his personal appearance is prepossessing, or whether his social attainments render him desirable, all of these questions are quite frequently weighed more carefully in the balance than these others: is the man a scholar, and can he teach? If he is a scholar, unless he has some good friends to speak for him, the presumptions are all against him. It is assumed almost as a matter of course that he can not be also a good teacher, and it seems practically certain that he can have no executive ability. Unless the photographer has been especially kind to him, his looks will probably not be satisfactory.

To return, for a moment, to the question of teaching ability; this is certainly one of the important points to be considered in the making of many and perhaps most appointments. But what methods have we for obtaining any positive or reliable information on that point? I think you will all admit that in most cases the evidence on that score might as well be dismissed; it usually consists of the statement of a few persons who may or may not be qualified to judge, and who may or may not know anything about the qualifications of the candidate as a teacher.

I wish to pass in review, rapidly, the methods employed in other countries in making university appointments, so far as I have been able to discover them.

The German system is fairly familiar. The faculty concerned makes recommendations to the minister of public instruction. There is no systematic and public canvass for the purpose of ascertaining the best man; the responsibility of making the recommendation is not fixed upon any particular man or group of men, but upon the faculty as a whole. Since the deliberations of the faculty are not public, any criticism of an appointment once made can not with any degree of certainty be directed toward any particular member of that body. While the system is, I believe, far better than our own and has in most cases given good results, it has often worked great injustice, making possible discriminations for personal or other reasons which under a better system might have been avoided.

I wish I could speak to you about an English system. But my attempts to find out about it have only led me to conclude that no such thing exists. Each of the universities in Great Britain apparently has its own methods of procedure in selecting its officers of instruction; each of the colleges which forms a part of the university again

has a different system, and the methods vary considerably even within the same institution for appointments of different grades. My source of information, one of the professors of Cambridge University, assures me that it would be a very formidable task to attempt to enter upon a comparative study of the methods of appointment in the English universities. Speaking of Cambridge, he says: "Certainly, for any trustworthy information about this place, a small pamphlet (perhaps it might not be small) is required." Under these circumstances, I feel compelled, in my discussion, to cross the channel to France, where a very simple and effective method is in operation.

The instructing staff of a French university is composed of professors (*professeurs titulaires*), *chargés de cours*, whom we shall here call assistant professors for the sake of convenience, and *maitres de conférences*, whom we shall call instructors. The latter conduct their courses under the direction of a professor, the subject being frequently assigned to them by such a professor. The assistant professor conducts his course independently, being temporarily in charge of a professorial chair; he therefore plays the part of a professor without having professorial rank. A limited number of these assistant professors may be appointed *professeurs-adjoints* (let us say associate professors). This distinction affects neither the character of their work nor their salary, but merely gives them the right to take part in the deliberations of the council of the faculty. This council, composed of the professors and associate professors, has jurisdiction over a number of questions in which the faculty is interested, among others those concerning appointments. An associate professor, however, has no right to vote on the appointment of a full professor. Certain other matters are decided by the whole faculty (*Assemblée de la Faculté*), composed of all of its members, including also the instructors.

If a professorial chair in a French faculty of science is vacant, the council of the faculty may or may not declare officially the existence of a vacancy, after which the chair is filled temporarily for a period of varying length by a *chargé de cours*. The minister of public instruction then inquires of the council whether it wishes the chair to be maintained, suppressed or transformed. If the chair is maintained or transformed, the candidates, who must be at least thirty years of age and in possession of the doctor's degree, are given twenty days to hand in their applications, publications, recommendations, etc. After the expira-

tion of this period the faculty presents a list of two names (first and second choice) to the minister of public instruction. But there exists a body called "*Section permanente du Conseil supérieure de l'Instruction publique*," composed of a number of scholars and high officials of the ministry of public instruction. This committee likewise presents a list of two names to the head of the department of public instruction, who may legally choose either name on either list. It is possible, therefore, that the new professor may not be one of those requested by the faculty. But such cases are very rare and arouse violent protests when they present themselves. Generally the first choice of the faculty is appointed.

There is no law requiring the minister of public instruction to consult the faculty in the appointment of assistant professors and instructors. As a matter of fact, however, this is always done, and except in one or two cases the wishes of the faculty have always been respected.

This system, which has some strong points, has given satisfaction. Still it does not seem to differ very materially from the German method, and seems to me to be much inferior to the Italian, which I shall now proceed to describe.

If a professorship in an Italian university is to be filled, the fact is advertised a long time beforehand in the official journal of the department of education, notices to this effect being also posted on the bulletin-boards of the various universities throughout the kingdom, as well as in other appropriate places. Anybody who thinks that he has any claim upon the position may apply. His application must be handed in by a certain date. It must include an account of his previous career, accompanied by the proper documents, diplomas, etc., a list of his publications and five copies of as many of these as possible. Most of the other documents are also required in five copies, for a reason which will immediately become apparent.

In the meantime the faculties of all of the universities of the kingdom are asked by the minister of public instruction to present him with a list of five men, these to be members of a committee whose purpose it shall be to judge the applications and to make a nomination. Each of the universities thus registers its choice as to the five men whom it considers the most competent judges in the case. They are, naturally, all specialists in the subject of the vacant professorship or else in closely allied subjects. These lists of five are again printed in the official journal. Five of the ten men who receive the highest number of

votes, the vote of each university counting as one, are then chosen by the minister of public instruction as members of the committee.

The responsibility for a selection now rests upon this committee. Each of the members individually examines the applications, and considers the relative merits of the candidates. Finally the committee meets as a whole in Rome and decides upon a first, second and third choice for the position. The minister of public instruction offers the position to the first choice; if he refuses, to the second, etc.

This system seems to me to eliminate, about as completely as any human contrivance may, the chances for injustice in an appointment. The complete publicity which attends the various steps in the proceedings, the fixing of the responsibility for a recommendation upon a committee of five of the most representative men of their profession, the democratic and in every way admirable manner of selecting these men, seem to give an absolute guarantee of the wisdom of the final choice. In fact it has worked admirably in practise, and it seems to me that this Italian system is the one which we ought to attempt to adapt to our needs in this country.

Gentlemen, I hope that the discussion of this evening will bear some fruit. If in our country there existed a central authority controlling all of our universities, we might make an effort to have such a system of appointments introduced by law. We are compelled to resort to a slower process, that of forcing a gradual change from our present methods by educating public opinion. But we are members of a great national organization, the American Mathematical Society, and I am going to ask you to support a motion to appoint a committee to investigate the possibility of improving the methods of appointments in our colleges and universities as far as mathematicians are concerned. I hope that you will support the motion; I hope that this committee will find a satisfactory solution of the problem, and that finally other national learned societies will follow our example, so as to improve the status of the American professor not only in mathematics, but in all other subjects.

To show you more in detail what kind of questions such a committee might investigate, I will give a few examples. Do not misunderstand me. I am not attempting to legislate for the committee, I do not hold tenaciously to any of the propositions which I am now going to advance. Their only purpose is to show that there are cer-

tain features of this problem which a society like ours can attack with some degree of success, and which would form a legitimate, if difficult, portion of its work.

Would it not be desirable, for instance, if every mathematical vacancy occurring in any of our colleges or universities were advertised in the *Bulletin*, accompanied by a statement of title and salary, grade, character and amount of work, as well as the date of appointment? It may seem very difficult, but may it not be possible to devise a scheme by means of which the society could put at the service of any institution requesting it, its advice in regard to the filling of any particular position? This might be done by means of a committee appointed for this purpose from year to year, or as in the Italian system for the making of one particular appointment. Several such committees might be appointed for the different regions of our country, whose vastness, of course, is one of the great difficulties to be overcome in the working out of such a system.

I have tried your patience long enough. I shall be satisfied if I have convinced you of the wisdom, not of any of the particular things which I have mentioned, but of the general policy of taking this matter under consideration. It is my honest opinion that the American Mathematical Society can render signal service to the cause of education and science in this manner. I feel convinced that it is our duty as free and independent men, as citizens of the academic world to take this step, which may lead toward a better condition of affairs, where merit will receive its just reward, where all proceedings will be open and frank, where there will be no place for incompetence and injustice.

E. J. WILCZYNSKI

THE UNIVERSITY OF ILLINOIS

GENERA WITHOUT SPECIES

NOTWITHSTANDING the great value of the International Code of Zoological Nomenclature, and the care with which it has been compiled, there remain several important points upon which those professing to follow the code are disagreed. In part, these are due to deliberate omissions, resulting from the impossibility of securing unanimity; but some of them are supposed to be covered by the code, and yet opposite interpretations are made by good authorities. Probably the most serious question of the latter sort relates to generic

names proposed without any definite mention of species to be included under them. The controversy over "genera without species" is especially agitating entomologists at the present moment, because of a proposal to bring into use a number of names for the most common genera of flies, and thus greatly disturb the nomenclature of dipterology. Professor Aldrich has ably contended against this proposal, fortifying his opinion with the code; but another very eminent dipterologist reaches exactly the opposite result, also using the code.

The matter is one which concerns all zoologists and botanists, and whatever may be the ultimate decision regarding it, it will be generally admitted that it is of the highest importance to determine current opinion, as a step toward securing unanimity. With the editor's permission, I will ask for a post-card vote from working zoologists and botanists, and will publish the lists of names in *SCIENCE*. The vote is asked on the question whether a generic name published without any mention of included species is to be regarded as valid, even though it is accompanied by a definition or diagnosis.¹ It has seemed to me that names so published were rejected by the code, because article 25 states that one of the conditions of the validity of a generic name is "that the author has applied the principles of binary nomenclature." This means, as I understand it, that he must not merely believe in those principles, or apply them elsewhere, but he *must apply them to the case in hand*, to the proposed new genus. If this is correct, I am totally unable to see how he can do this without designating any species by name. In absolute strictness, he ought not merely to designate an included species, but also make the proper combination with the generic name. This is recommended by the present code, but not made obligatory.

Those who take a different view, support their contention by reference to article 2 of the code, which states that "the scientific

¹ This does not include names proposed (on account of preoccupation) to replace others which already have included species. Such cases are covered by the code.

designation of animals is uninominal for subgenera and all higher groups." This, it seems to me, merely states the obvious fact that the names of subgenera, genera, families, etc., are single words; it does not appear to offer any opinion as to the proper manner of publishing the various designations. Who can define a genus, except as including species; a family, except as including genera; an order, except as including families? It is not possible to upset our fundamental conceptions of these things, any more than it is possible to write sentences without words, words without letters of the alphabet. A genus without species has no type, no content, and apparently has no place in our systems of classification.

On the other hand, various generic names, first proposed without any designated species, have later been given full validity by the designation of specific types, and the publication of the necessary combinations. Some writers have held that when the first mention of an included species was made by some author other than the original one, the generic name should be credited to the author citing or describing the species. I think this should not be strictly necessary, but that while the generic name must be dated from the later publication, it may properly be credited to the original writer, whose work may be considered to be included and republished in the validating work. This is a matter on which opinions will differ, and as it does not affect the names themselves, it is not of the first importance. Another difficult class of cases is that in which a generic name has been proposed with the name of an undescribed species. The late Dr. Ashmead has left us a large number of such genera. If the genus was also without definition, both generic and specific names would be *nomina nuda*; but I have ventured to hold that any diagnosis of the genus might also be interpreted as a diagnosis of the species (only one being mentioned), and hence both generic and specific names would be available for adoption.

UNIVERSITY OF COLORADO,
BOULDER, COLO.

DR. WILLISTON ON "THE FOSSIL TURTLES OF
NORTH AMERICA"

IN SCIENCE of December 4, 1908, Dr. S. W. Williston has published a review of my book, "The Fossil Turtles of North America." This review showed as much appreciation of the merits of the book, and as much leniency towards its shortcomings, as its author could desire. However, one or two matters referred to by Dr. Williston seem to require notice; and this is here respectfully presented.

Dr. Williston takes issue with my division of the turtles into the Athecæ and the Thecophora. To this I will say that unless the early turtles separated primarily into the ancestors of the two groups mentioned, these two suborders are not at all worthy of recognition.

As to the resemblances between the leather-back and the other sea-turtles, I will, to illustrate, consider the flippers. The limbs of the primitive turtles were, I believe, not greatly different from those of the snapper, for example. Inasmuch as the ancestors of the leather-back and those of the other sea-turtles started with the same form of fore limb and on entering the water employed this limb in the same way, it is not strange that their descendants have closely similar flippers. The fore limbs of the Trionychidæ have certainly been independently developed, and yet they are being modified in the same direction. Those of *Carettochelys* are another example. If a thoroughly aquatic pleurodire shall ever be discovered it will doubtless have similar fore limbs.

As regards the two dermal coverings of the primitive turtles, I may remark that the early reptiles probably had as great need of armor as their modern descendants. A modern crocodile seems to have need of only a single layer of dermal bones, the so-called abdominal ribs, in the lower wall of its belly; but a cayman requires, in addition to this, an armor of closely jointed bony scutes. The leather-back itself actually possesses the two bony coverings in question. Ventrally the plastron of dermal bones is covered by rows of osseous scutes, while on the upper surface the nuchal

bone is found to be overlaid by a portion of the mosaic-like bony armor. Who is to say that never were there under this mosaic of the upper surface also peripheral bones, and even costal plates?

Dr. Williston is certainly correct in holding that the elements that I have called fascia bones are of dermal origin. The dermal bones that had sunken beneath the skin I thus named, in order to distinguish them from a more superficial stratum.

As evidences for the existence of two dermal bony coverings in the primitive turtles I present for consideration the fact that the leather-back has as many longitudinal zones of bony scutes as the most generalized turtles have of horny shields, and the additional fact that the horny shields do not coincide with the bones which they overlie, but break joint with them.¹

Dr. Williston says that "*Toxochelys* possesses neural ossicles, while the nearly related and less aquatic *Porthochelys* is without them." In like manner, the alligator snapper possesses a series of supramarginal horny shields, an ancient inheritance, while the common snapper has lost them. *Porthochelys* retained the nasal bones, but *Toxochelys* did not.

My friendly reviewer is in error when he states that I hold that in *Toxochelys* there are only vestiges of the inner layer of dermal bones. The nuchal, the costal plates (except that part belonging to the true ribs), the peripheral bones, and the whole plastron, belong to the inner layer.

Dr. Williston mentions the fact that I have omitted mention of two turtles that have got into literature. One of these is from the Dakota sandstone of Kansas, a formation that has furnished no other remains of the order. This specimen² is the cast of the cavity of the shell, with indications of some of the ribs. The relationships of the turtle are indeterminate and fortunately no name has been given the specimen. The other turtle referred to was originally briefly described by Dr. Willis-

¹ See *American Naturalist*, XXXII., 1898, pp. 929-948.

² *Trans. Acad. Sci.*, XVI., 1899, p. 67, pl. iv.

ton himself.' It had been discovered in the Benton beds of Kansas and is stated to consist of some fragmentary ribs and a part of a humerus. The species is supposed to be related to *Protostega*, but here again no name was imposed on the specimen. Dr. Williston pays me the compliment of regretting that I did not describe these materials, with which he could do little himself.

QUOTATIONS

AMMUNITION AGAINST THE ANTI-VIVISECTIONIST

As antagonism to vivisection is a form of incurable insanity, those who suffer from it are wholly indifferent to argument or facts, and their delusional convictions urge them irresistibly to constant repetition of the same mad acts, quite regardless of consequences to themselves or others. Hence is it that year after year these unfortunate people renew their efforts to secure legislative interference with or prohibition of the experiments with living animals upon which the progress of medical science depends and without which medical practise would be reduced to blind, or at least dim-eyed, empiricism.

That the anti-vivisectionists always find somebody to introduce their bills is a sad commentary on the intelligence of legislators, but this year, as so often before, the battle with well-intentioned ignorance must be fought again. There are now a few more triumphs over disease with which to confront the wild assertions and accusations of the agitators, but dependence must still be placed on arguments the adequacy of which has already been proved a hundred times—so often, indeed, that many of the same people whom they long since convinced have half forgotten essential parts of the evidence upon which the animal experimenters rely as a defense from the hampering restrictions that unreasoning sentimentalists would impose upon one of the most unselfish and successful classes of workers for the common good.

¹ *Kansas Univ. Quarterly*, I., 1902, p. 247.

There is danger in this forgetfulness, and to meet it the Committee on Experimental Medicine of the New York State Medical Society has begun the publication of a series of leaflets setting forth clearly and briefly the scientific and medical side of the vivisection controversy. One by Dr. E. L. Trudeau deals with "Animal Experimentation and Tuberculosis," another by Dr. James Ewing takes up with cancer research, and a third by Professor F. S. Lee treats of "The Sense of Pain in Man and the Lower Animals." Dr. Simon Flexner's contribution tells what vivisection has accomplished in the war against infectious diseases, and Dr. S. J. Meltzer discusses "The Function of the Thyroid Gland—an Important Chapter of Modern Medicine." A leaflet of a different kind is one giving eminent lay opinions, among those quoted in it being ex-President Eliot, of Harvard; President G. Stanley Hall, of Clark University; President E. H. Capen, of Tufts College; Bishop William Lawrence, of Massachusetts, and Dean Hodges, of the Cambridge Theological School. Dr. William H. Park takes up the great subject of "Diphtheria," the disease which would still be slaying its thousands had it not been absolutely conquered through vivisection alone.

Copies of these and other leaflets can be obtained upon application at the Academy of Medicine, 17 West Forty-third Street. They are intended especially for physicians, but they are full of ammunition which anybody can use in answer to silly talk about the cruelty or the uselessness of a method of investigation which is neither the one nor the other, but is, on the contrary, one to which animals and men alike are incalculably indebted for relief from pain.—*New York Times*.

AN IDLE CHALLENGE

THIS characteristic communication comes to us from the president of the Anti-Vivisection Society:

TO THE EDITOR OF THE EVENING SUN—Sir: Regarding your editorial attack in *The Evening Sun* of January 27 upon a leaflet issued by this society, I would say that I should be glad to have you attempt at our mass meeting (to be held at Car-

negie Lyceum, February 3, 8 P.M.) to sustain your assertions against its accuracy. Miss Lindaf-Hageby will be glad to show you that you are in great error. Very truly yours,

DIANA BELAIS

New York, January 31.

We have received a similar letter from a woman who says she wrote the leaflet. She shall be nameless. It is typical of the light-hearted irresponsibility of the anti-vivisectionists that neither the woman who is responsible for the publication of the leaflet nor the woman who boasts of having penned it offers the least defense of her part in the matter. Instead we are told that a certain young woman from England "will be very pleased to meet any one in debate." This young woman, we may remark, was joint author of a scandalous publication entitled "The Shambles of Science," which the publisher was compelled to withdraw from circulation several years ago, with a public expression of "sincere regret for having printed and published the book in question." We have no desire to enter into any controversy with this woman, who confesses that she has some difficulty in finding opponents at debate in the country of her adoption—a circumstance which does not astonish us in the least.

Mrs. Belais boldly proclaimed the other day that no "unjustified assumptions or allegations" were published by her precious society. We picked up a leaflet and extracted this single passage: "Pasteur and his followers increased a very rare disease called rabies, and are making fortunes out of the anti-rabic virus." To call this an "unjustified assumption" is to state the case mildly. It is nothing less than an infamous and malicious lie. And we maintain that it is a disgusting spectacle to see so great a benefactor of the human race as Pasteur treated in this frivolous manner by a parcel of unscrupulous women.—*New York Evening Sun*.

SCIENTIFIC BOOKS

Biology and Its Makers. By WM. A. LOOY.
With portraits and other illustrations.
New York, Henry Holt & Co.

It was the purpose of the author of this book to give "an untechnical account of the rise and progress of biology" which "would be of interest to students, teachers, ministers, medical men and others"; "to bring under one view the broad features of biological progress and to increase the human interest by writing the story around the lives of the great leaders." "The portraits [82 in number] with which the text is illustrated embrace those of nearly all the founders of biology." The scope of the volume is best seen from its table of contents:

Part I.—The Sources of Biological Ideas Except Those of Organic Evolution. Ch. I. An Outline of the Rise of Biology and of the Epochs in its History. Ch. II. Vesalius and the Overthrow of Authority in Science. Ch. III. William Harvey and Experimental Observation. Ch. IV. The Introduction of the Microscope and the Progress of Independent Observation. Ch. V. The Progress of Minute Anatomy. Ch. VI. Linnæus and Scientific Natural History. Ch. VII. Cuvier and the Rise of Comparative Anatomy. Ch. VIII. Richet and the Birth of Histology. Ch. IX. The Rise of Physiology—Harvey, Haller, Johannes Müller. Ch. X. Von Baer and the Rise of Embryology. Ch. XI. The Cell Theory—Schleiden, Schwann, Schultze. Ch. XII. Protoplasm and the Physical Basis of Life. Ch. XIII. The Work of Pasteur, Koch and others. Ch. XIV. Heredity and Germinal Continuity—Mendel, Galton, Weismann. Ch. XV. The Science of Fossil Life.

Part II.—The Doctrine of Organic Evolution. Ch. XVI. What Evolution is: The Evidence upon which it Rests, etc. Ch. XVII. Theories of Evolution—Lamarck, Darwin. Ch. XVIII. Theories Continued—Weismann, De Vries. Ch. XIX. The Rise of Evolutionary Thought. Ch. XX. Retrospect and Prospect. Present Tendencies in Biology. Reading List. Index.

This book is of much value and should be placed upon the shelves of all school libraries. Biologists will find it a convenient book of reference. Few readers will be so well informed that they will gain no information from its pages. Of especial value are the portraits, many of which are rare and unfamiliar.

The volume is a compilation. Its author makes free use of other studies in the same field, and accepts, for the most part, the gen-

eral judgment as to the men whose work he describes. These judgments and characterizations are occasionally rather naïvely expressed, but the reader is not often inclined to take exception to them, though in certain instances one must do so. For example: The somewhat extended reference to Ehrenberg's work on the protozoa and the very brief mention of Stein is hardly consistent with the fact that Ehrenberg's work, though extensive, was inaccurate and as a whole made no such valuable contribution to our knowledge of this group as did Stein. Richard Hertwig's influence upon the progress of protozoology has hardly been second to that of Bütschli. In the chapter upon classification no emphasis is laid upon the recognition of the sponges as clearly distinct from and sharply contrasted with all the other metazoa. In the discussion of advances in cytology no mention is made of the evidence that the male and female parents are equipotential heredity, nor is there any reference to the work of Richard Hertwig, Schaudinn and others upon the presence and behavior of generative and vegetative chromatin in the cell, though these subjects are surely as important as recent studies of cell-lineage and regeneration which are mentioned. One wonders if the author's confidence that vitalism is a wholly mistaken conception (p. 181) is justified. Are psychic phenomena chemical and physical?

The descriptions of the men and their work and place in the progress of biology are not so vivid as they are, for example, in Foster's "History of Physiology," but this doubtless is in part due to the greater scope of the book and its necessarily briefer treatment of each man and his period. The treatment impresses one not as masterful, but as faithful, and in general sound. In its reference to modern workers, American students receive disproportionate mention, but in a volume designed for American readers, this is perhaps not unnatural.

The second part, dealing with the doctrine¹

¹ Theory might be a better word, for the word doctrine carries with it, not logically but actually, a little of the flavor of the word dogma.

of evolution, is not so satisfactory as Part I. The author might have been more successful in his attempt to condense into brief statement the essential features of the theory. He might well have included reference to isolation as a factor in evolution, and perhaps, even in so condensed a treatment as this, organic selection might be mentioned. The presentation of Mendelism (p. 316) would hardly be clear to any one not already familiar with the subject. The statement (p. 389) that "sexual selection is almost wholly discredited by biologists" is of course a mistake. Probably all recognize its past importance among human kind, and some believe that it will in time become of greatly increased importance in human evolution.

A few inaccurate statements, and some of doubtful truth, might well be modified in a second edition. Weismann's theory of heredity was presented in his essays upon heredity some years before the appearance of his volume "The Germ Plasm" published in 1893. Is it true that "Davenport, Tower and others have made it clear that species may arise by slow accumulations of trivial variations, and that, while the formation of species by mutation may be admitted, there is still abundant evidence of evolution without mutation?" It seems, on the contrary, increasingly probable that fluctuating variations do not form a basis for the evolution of new species. It is difficult to see the author's meaning in his statement (p. 404) that "neither mutation nor natural selection is a substitute for the doctrine of the continuity of the germ plasm," or in the statement (p. 405) that "the body cells are not inherited"; and we can not but object to the form of the statement (p. 406), that "natural selection presides over and improves variations arising from mutation," and to the last phrase in the sentence (p. 316). "In this country the experiments of Castle, Davenport and others with animals tend to support Mendel's conclusion and lift it to the position of a law." Sexual selection in the sense now accepted, though not in Darwin's usage, has no relation to the "law of battle" (p. 413). In view of evidence presented by Poulton in his address at

the Darwin celebration in Baltimore last Christmas, there is need of modifying the statement (p. 414) that "it is altogether likely that Lamarck was wholly unacquainted with" [Erasmus] "Darwin's work, which had been published in England." Charles Darwin lived at Downe not Downs.

Is it true (final chapter, p. 441) that experiments with "artificial fertilization by changes in osmotic pressure . . . have greatly altered opinions regarding the nature of fertilization, and of certain other phenomena of development," or (p. 442) that "recent advances in physiological chemistry have greatly widened the horizon of our view regarding the nature of vital activities"? Would not both statements be stronger if more modest in their claims for the results of recent research in these most important fields? It is doubtful if even in a popular book of this sort it is justifiable to attempt to state the duration of geologic periods in years (cf. p. 844-5).

One finds in the book some phrases and sentences whose form is not beyond criticism—(p. 443) "studies of a pathological character"; (p. 294) "sheep and other cattle"; (p. 383) "pigeons and other fowls"; (p. 429) Wallace is said to be "notable for the publication of important books, as the 'Malay Archipelago,'" etc.; the phrase "fossil life," is frequently used, once it appears as "fossil vertebrate life"; it seems strange (p. 337) to refer to Leidy, Cope and Marsh as "these gentlemen" instead of these men. They were big enough to deserve the bigger word. Why does it seem strange (p. 335) to speak of Huxley shedding light "in the province of paleontology," for the phrase is good and is exactly what is meant; or why does one smile when the author refers (p. 190) to Johannes Müller as "one of the lights of the world."

A few errors which escaped the proof reader will doubtless be corrected in another edition. The index is so incomplete as to lessen the usefulness of the book. Many important subjects and men treated in the text are not mentioned in the index. Such a historical account does not soon become out of date. It will surely have a number of editions and its minor defects can readily be removed.

Professor Locy has done good service in bringing together into one volume information as to the development of all the broader phases of biology and in presenting a general view which is, on the whole, so sound and well balanced.

The Young of the Crayfishes Astacus and Cambarus. By E. A. ANDREWS. Smithsonian Contributions to Knowledge. Vol. XXXV. Pp. 1-80, pls. I.-X. Washington. 1907.

The European crayfish has been upon the whole exceptionally fortunate in its biographers, for with it are associated the names of such excellent observers as Réaumur, Roesel von Rosenhof, Rathke, Huxley and Reichenbach, whose combined work, and more especially that of Huxley, have made it a classical type in the teaching of modern zoology. It is accordingly a little surprising that the American species, especially of *Cambarus*, which everywhere abound, should have escaped that careful analysis of their habits and development which their importance would seem to demand, until a series of papers extending to the monograph under review was begun by Professor Andrews five years ago.

The distribution and description of the many species, as well as the embryology and physiology of the common *Astacus fluviatilis* of Europe form the subject of a rather extensive literature, while the behavior and development of the young after leaving the egg, and the interesting family life first described by Roesel more than a hundred and fifty years ago, have hitherto received but scant attention. As the author suggests, this neglect may be attributed in some measure to the lack of a complete metamorphosis for which the crayfishes have been distinguished from the time of Rathke. Since their young are invariably hatched in a form which closely resembles the adult, greater interest has been taken in the life histories of marine crabs and shrimp, which, as a rule, hatch from

small eggs and must pass through a long and fascinating series of changes before the adult form and habit are attained. It should be added, however, that in the modern zoologist the lure of the sea is strong, even when crayfish abound in his back-yard and burrow all over his lawn. Roesel indeed complained of the neglect which obscured the life of common things in his day, and recalled the old Latin proverb to the effect that what is daily seen is little heeded.

In the present monograph, as well as in his earlier papers, Professor Andrews has thrown a light on many obscure questions, and has probably added more to our knowledge of the crayfish family life and general natural history than all previous observers combined.

For the first time the habits and development of an American species of *Astacus*, from the Pacific coast, are described, while its young have been reared to a length of two inches and an age of five months, when they have molted twelve times, and reached essentially the adult state. The behavior of these young is subjected to a careful analysis, and the text is illustrated by a series of excellent pen drawings showing in detail the slight but important changes which ensue in the body proper and its nineteen pairs of appendages during the first three stages, or until the young have become independent of their mother. Careful drawings to a uniform scale have seldom or never been made to represent the complete metamorphosis of any crustacean, and students of this important class will appreciate their value in the present case.

The habits and development of *Cambarus affinis* are treated in a similar descriptive and pictorial way, and the author devotes a chapter at the end to the weighing of the differences and agreements found in the two genera, and to certain speculations upon the possible origin of their diverse dependent stages and family life.

Astacus leniusculus lays its eggs, to the number of five hundred in the cases observed, in autumn, probably in October, and carries them attached to its pleopods all winter; these eggs are dark in color, and very large

for a crustacean, having a diameter of two and one half millimeters, which accords with the precocious character of the young at birth. Hatching took place in late April and early May, and extended over several days. The young leave the egg in a relatively advanced but quite helpless condition, and if expelled from the mother, as in the case of the marine lobster, they would perish from lack of parental care, for they present a curious compound of embryonic, larval and adult characters. It is at this juncture that the peculiar family life of the crayfish has been developed to tide the young over a helpless period of infancy to complete independence, and the account of this interrelation of parent and child, and the correlated structures and instincts upon which it is based constitute the most interesting part of Professor Andrews's work.

The family relation in this *Astacus* endures for over a fortnight or until the little crayfish has molted for the second time, and is dependent upon a complicated chain of events, which suggests the story of the old woman who went to market to buy a pig. If the egg-stalk does not adhere to a "hair" of the parental swimmeret or to another egg; if the two egg-shells are not themselves adherent; if a certain delicate thread, which is spun as it were from an embryonic molt shed at hatching time, does not itself stick on the one hand to the telson of the young, and on the other to the inside of the inner egg-shell and thus tether the little one to its mother; if, again, a little later, when its leading string has broken, this young one has not been enterprising enough to seize and "hook on" to some part of the egg-glue with its great forceps, the tips of which have been bent into fish-hook form—it comes to certain grief. The result is fatal, at whatever point the chain weakens and snaps.

A few hours after hatching the helpless little crayfishes, still dangling from the "telson-threads," which secure each to the parent, begin to flap their abdomens, and to open and close their big hooked claws. In this way they manage to seize the old stalk of

the egg, and with hooks embedded in its tough chitinous "glue" they hold on literally "for dear life," often grasping the same stalk with both chelæ. So strong was this seizing and holding instinct that the young when forcibly separated from the mother would sometimes lay hold of a suspended string, and were thus successfully reared until the period of dependence was over. Once fixation with the claws is successful, the telson-thread breaks and the young remain thus attached by the claws alone for a period of from four to thirteen days, according to condition, when they molt to the second stage.

At the second molt this crayfish is for the first time free, and soon begins to descend the parental pleopod, climbs over its mother's body, and makes short excursions in the neighborhood, returning again and again to the alma mater and the family brood. Hitherto it has been sustained solely by the generous supply of yolk inherited from its egg-state, but since the egg-stalks and cases, as well as the cast skins which remain attached to the mother, disappear at this time, it is thought that they are eaten by the young and constitute the first direct food that they receive before beginning to forage for themselves.

The second stage *Astacus* develops a strong climbing instinct; it is brilliantly arrayed in red and blue pigments as well as the colors which the transparent skin transmits from liver and yolk. The swimmerets are functional, and the appendages generally are garnished with numerous sensory setæ; but the powerful "propeller" or tail-fan is not completed by the liberation of the sixth and largest pair of pleopods until the third stage is reached. Then the little crayfish becomes very active, voracious and pugnacious, frequently losing its limbs at the "breaking joints" and as freely regenerating them. At the fourth stage the rudimentary first pair of pleopods make their appearance, and probably in the males only.

The *Cambarus affinis*, which Professor Andrews has studied with marked success, lays its eggs in March or April, and carries them

about seven weeks. Its eggs are smaller and rather more numerous than in the *Astacus*, and the young are correspondingly less advanced at the time of hatching. They do not leave their mother until the third stage, but are associated with her for about two weeks only, or for nearly the same length of time as in *Astacus*. In this case also at hatching the young are tethered, and prevented from escaping from the mother, but by an "anal thread" of a peculiar character. When this young escapes from the egg it leaves behind it a larval cuticle or molt, which sticks at two points only, on the side of the mother to the egg-membranes which are adherent to her, and on that of the child to a portion of the intestine where its cuticular lining is not at first set free. As a result of the tension this embryonic molt is stretched and crumpled with a tendency to turn the abdominal part inside out. This telescoping and partial inversion of the discarded cuticle is checked by the flat molted plate of the telson with the resultant production of a narrow creased ribbon, the "anal thread," which is firmly fastened to the intestinal wall.

The young of this crayfish attain a length of two inches during the first summer, when they may be fertilized by a male of corresponding age and lay fertile eggs in the following spring. In one case a female which was reared from the egg laid eggs herself in two successive seasons, when about one and two years old, and when somewhat more than two and three inches long respectively. Andrews remarks that since the young of this *Cambarus* reared in captivity not only laid fertile eggs, but since this was repeated in the next or third generation there would seem to be no obstacle to the domestication of this crustacean and rearing of it upon an extensive scale.

The first two stages of the young are thus not only peculiarly modified for association with the parent, but in some way unknown, correlated structures of a most delicate kind, not to speak of instincts, have arisen in both to bring this about. These may be compared to the first three stages of the lobster, in

which the young is not only a true larva, but pelagic. The lobster also makes good use, but in a different way, of a "lost larval molt," which is shed at the time of hatching. In this case also the molt sticks to the mother, that is, to the inside of the inner egg-membrane or chorion, and by being slightly adherent to the setæ or swimming hairs of the larva, helps to pull them out or evaginate them, and thus bring them into position for immediate use. To escape merely from its egg-shells, without losing in the proper manner this inner cuticular molt, is as fatal to the lobster as the premature breaking of the telson or anal threads would be to the crayfish.

The third stage in the crayfish corresponds approximately to the fourth stage in the lobster, in which the animal passes as if by a sudden leap into the adult-like form, but the transition is less abrupt in crayfishes since their most striking larval characters have been lost.

In giving up the free-swimming habits of their marine lobster-like ancestors, the crayfishes have apparently acquired their peculiar family life, and a "crawling instinct" would seem more in accord with the needs of many of the species which inhabit fresh water-courses liable to go dry, or which even burrow deep in the ground to find the necessary moisture.

The larval history of *Astacus* is thought to be "more primitive in having a more complete representation of a lost larval stage still evident in a complete cast cuticle within the egg." But this cuticle is apparently not homologous with that cast by the lobster at birth, the pre-pelagic stage of this form being represented by an egg-stage in *Astacus*. Again, since the family life is more completely developed in *Cambarus*, and the genus is more specialized than in *Astacus*, "we may therefore suppose," says Andrews, "that as *Cambarus* has migrated over the middle and eastern United States it has become split up into the sixty odd species now found and in some, as in *Cambarus affinis*, has made more perfect the association of young and parent already present in the *Astacus* ancestor."

It is further suggested that the apparent relation between acquisition of family life and migration from the sea to fresh water may be illusory, since metamorphosis has already been reduced in the marine lobsters, and since in bays and estuaries which must have been first encountered this dependent relation would seem to be especially valuable.

While it is easy to speculate on the origin of the specific characters of crayfishes, and we might add of any animals whatsoever, he concludes that "the nature and the amount of differences of the hard parts and in the larval history that distinguish one kind of crayfish from another are such as to raise the question whether utility and natural selection have played any part in their formation or in their perfection. All the specific and generic characters of crayfish may be as useless as color differences, and they may have arisen suddenly perfected as we see them, or they may have progressed in certain lines for long periods of time independent of external agencies." Much more evidence is needed before we can conclude that the various parts and functions displayed "have ever in any manner been connected with utility to the species or with the survival or extinction of individuals. Until the contrary is proven we may therefore regard them as the unmeaning by-products of unknown activities in the living protoplasm."

Such criticisms as are suggested in the reading of this careful paper are of a minor character. It does not seem proper to describe the invaginate matrix cells of the epidermis which secrete the cuticular sheaths of spines or setæ as "glands," since all the superficial cells of the epidermis are chitino-genous. Further, it would appear to be less confusing to limit the use of the troublesome term "larva" to the first two stages of the young, and to designate as "adolescent" or "adult-like" those stages in which the adult characters appear most pronounced, unless we resort to some such cumbersome terminology as that proposed by Hyatt.¹ It is certainly objectionable to designate as "larva"

¹ SCIENCE, N. S., Vol. V., p. 167.

(p. 89) the older young, which have attained a length of over an inch and may be several weeks, or even months, old.

It might appear hypercritical to raise the question whether the walking legs of a higher crustacean like the crayfish have claws (p. 23). Huxley got around this difficulty by using the terms "double" and "single claws" for the forceps of the first three and the "nails" of the last two pairs of legs, respectively, which describe the conditions met with in the crayfish exactly. This, however, does not correct the inappropriate though technical use of the Latin word *chela* for the pincers alone.

It is certain that metamorphosis in the higher crustacea has been reduced or eliminated under very different conditions in the rather numerous cases in which a reduction has occurred, as seen not only in the common lobsters (*Homarus*), but in many deep sea shrimps, shallow water *Alphei* and terrestrial crabs (*Gegarcinus*). As regards the possible influence which conditions of life in fresh water may entail, it is interesting to note that metamorphosis has been practically eliminated, not only in the fluviatile crayfish, but also in *Palæmonetes varians* of Europe and in *P. exilipes*, of parts of the eastern United States, one of the few fresh-water genera of prawns known, and that in this case their immediate marine ancestor, the common little *Palæmonetes vulgaris*, has a metamorphosis both long and complete.

FRANCIS H. HERRICK

Astronomy of To-day. By OECIL G. DOLMAGE, F.R.A.S. Pp. xvi + 368, with 45 illustrations and diagrams. Philadelphia, J. B. Lippincott. 1909.

The fascination of astronomy seems as strong to-day as in the distant past, when some knowledge of the heavens was essential to the every-day life of the traveler and the householder. To-day the compass, not the pole-star, guides the voyager across the seas and deserts; the watch and the calendar have replaced as timepieces the sun and the constellations, yet the interest in matters astro-

nomical never wanes. To a large extent this interest is due to the ever-widening fields of astronomical research. Fifty years ago astronomy was practically confined to a mathematical explanation of planetary motion, with a few dry statistical facts concerning the size, shape and mass of the various bodies. To-day astronomy deals with the bodies themselves, with their physical conditions, their life histories, and the probable stages of their evolution. Physics and chemistry are the tools with which an astronomer of to-day works, photography and the photographic plate have replaced the eye and the hand in picturing the wonders of the heavens. Now this new astronomy appeals more directly to the popular reader than did the mathematical astronomy of the past century: one is more interested in knowing what a body is and how it came into being, than in learning the minute details of the path it is describing. That such is the case and that the interest in things astronomical is general, is evidenced by the increasing number of popular and non-technical books on various astronomical subjects.

The field of astronomy to-day, however, is so broad, it covers so much ground, that it can hardly be adequately treated of in a single small volume. The space in even a large book hardly suffices to give proper account of a single minor division of the great science. A single volume, which attempts to cover the entire field, can be but little more than a general index, pointing out to the reader the divisions of the subject, the relative importance of each, sketching in a broad way the principal facts and the underlying theories of celestial development, and indicating who the real workers are and where special details and facts can be obtained.

Now in some of these particulars the well got up and attractive book of Mr. Dolmage falls short of what such a book might be. If we regard the amount of space devoted to a subject as indicating to a certain extent the importance of the subject, then this volume shows some rather remarkable conceptions. For us the sun is undoubtedly the most important body in the heavens, it is the center

from which is derived the heat, the energy, the life of the earth. The countless myriads of stars and the numerous planets could be blotted out of existence without sensibly affecting our daily life; but if the sun ceased to shine the days of the world would be numbered. Again, the sun is a typical star and only by a minute and careful study of the solar constitution can we ever hope to derive some knowledge of the condition of the stars and the course of stellar evolution. Yet Mr. Dolmage devotes but eighteen pages to the study of the sun, and gives twenty-five to the moon and forty-four to eclipses. Comets, the ephemeral by-products of the solar system, are given just as much prominence as the sun itself. Again, the lines along which modern research is progressing are not clearly set forth, and the reader is often left in doubt as to who are the real workers and leaders in astronomical thought. Too much prominence is given to the opinions of writers of scientific fiction; it is certainly an innovation in a serious work to find H. G. Wells so freely quoted.

The book is well written and well printed, and it may serve the purpose described by its subtitle as "a popular introduction in non-technical language." The illustrations are well selected and many of the photographs are beautifully reproduced. The three views of the moon, taken from photographs made in the Paris Observatory, are exceptionally well rendered in the plates.

CHARLES LANE POOR

The Royal Society Archives: Some Account of the Letters and Papers of the Period 1741-1806, with an Index of Authors. Compiled by A. H. CHURCH, D.Sc., F.R.S. Pp. 73. Oxford, 1908.

A valuable aid to the student who may wish to consult the original communications made between 1741 and 1806 to the Royal Society of London has been prepared by Dr. A. H. Church, to whom we are already indebted for a manuscript calendar of the collection of guard-books designated as "Classified Papers." An earlier collection of letters addressed to the society or its officers, and comprised in

forty-eight volumes, was indexed by W. E. Shuckard in 1840. The third set of guard-books, which comprises both letters and papers, consists of 127 volumes and these have been grouped in twelve decades, the letters and papers in each of these being numbered consecutively. The series is designated "Letters and Papers." Although most of the material of the letters was published in the *Philosophical Transactions* of the society, they were edited to a considerable extent, and much of the personal note was removed in this way. From among many interesting items noted by Dr. Church in his pamphlet, we select the following:

Decade I., No. 403. In a letter dated May 4, 1745, R. A. F. de Réaumur says:

I heartily wish there was in the world as strong a moral attractive power as there is a natural one that might dispose our two nations particularly to seek to unite by mutual acts of friendship and good will.

Decade II., No. 198. An unpublished letter of Benjamin Franklin, dated February 4, 1750, describes certain experiments in killing hens and turkeys by the electric current. Franklin proceeds to relate his personal experience of an electric shock from the apparatus employed:

In making these Experiments, I found that a man can without great Detriment bear a much greater Electrical Shock than I imagin'd. For I inadvertently took the Stroke of two of those Jars thro' my Arms and Body, when they were very near full charg'd. It seem'd an universal Blow from head to foot throughout the Body, and was followed by a violent quick Trembling in the Trunk, which went gradually off in a few seconds. . . . My Arms and Back of my Neck felt somewhat numb the remainder of the Evening, and my Breastbone was sore for a Week after, as if it had been bruised.

Decade II., No. 494. A letter in Latin from Linnæus, acknowledging his election to the society. A facsimile of this letter is given in Dr. Church's pamphlet.

Decade III., No. 117. A letter, also in Latin, from Josef Stepling, concerning a shower of meteoric stones that fell near Strkow in Bohemia, July 8, 1758. One of these aerolites is now in the British Museum.

Decade IV., No. 84. A letter from the Rev. Wm. Hirst dated Fort St. George, E. Indies, February 25, 1761, offers a careful drawing of a leaf-insect with the remark:

Nature seems to have provided for its security by giving it so strong a resemblance to Blades of Grass among which it is frequently found.

Decade V., No. 60. In a letter dated St. Petersburg, 21 Oct./1 Nov., 1768, in which Leonard Euler alludes to his blindness, occur these words:

As the British Parliament were pleased to reward so generously the slight researches which I had made on the Lunar Theory.

Decade V., No. 80. A letter, dated Rio de Janeiro, November 30, 1768, from Captain James Cook to Dr. Morton, secretary of the Royal Society, wherein Cook writes:

The account we gave of our Selves of being bound to the Southward to observe the Transit of Venus (a Phenomena they had not the Idea of) appeared so strange to these narrow-minded Portuguese that they thought it only an invented Story to cover some other design we must be upon.

Decade VI., No. 40. On March 24, 1774, a paper was read by Edward Spry, a well-known surgeon of the day, explaining his antiseptic treatment of amputations by the use of a special dressing, "preventing putrescence."

Decade VI., No. 119. Professor John Winthrop, of Cambridge, Mass., described, in a letter dated November 16, 1774, a pictorial hieroglyph inscribed on a rock twenty miles south of Boston, on the Taunton River.

Decade VIII., No. 1. Writing to Sir Joseph Banks, Sir William Herschel names a new star, *Georgium Sidus*.

Decade IX., No. 27. A paper of 19 pages communicated by Pierre Laporterie under date of August 14, 1786, and entitled "*Saphir crystal, susceptible de l'étoile a six raions*"; not printed.

Decade X., No. 65. Paper by Sir William Herschel on the "Quintuple Belt of Saturn"; read December 19, 1793; not printed.

Decade X., No. 70. Letter of Alessandro Volta regarding Galvani's discoveries; read in January, 1794; not printed.

Decade XI., No. 93. An account of the Andaman Islands and their inhabitants, by

Captain Archibald Blair. 82 pages and map; read April 4, 1799.

Decade XII., No. 28. Description of what he calls a pulmonary calculus, by Philip Crampton. This concretion was seven inches in diameter and weighed 845 grains.

In addition to the names mentioned above, the following are especially noteworthy: John Abernethy, Abbé Jean Jacques Barthélemy, G. B. Beccaria, Comte de Buffon, Charles Burney Mus. Doc., Hon. Henry Cavendish, Duc de Chaulnes, Richard Chenevix, Erasmus Darwin, Sir Humphry Davy, Sir William Hamilton, Rev. John Lightfoot, Jean Hyacinthe de Megalhaens, P. L. M. de Maupertius, Rev. Joseph Priestly. The index contains more than fifteen hundred names, and enables the student to refer without delay to each paper or letter in the collection.

A REVISED CLASSIFICATION OF THE NORTH AMERICAN LOWER PALEOZOIC¹

CLASSIFICATIONS of stratigraphic subdivisions are bound to change with the expansion of our knowledge of detail, so that the most recently accepted must still be regarded as a tentative one, to be replaced by a better one when needed, and the knowledge of facts warrants it. The generally accepted classification of the Lower Paleozoic of North America, proposed by Clarke and Schuchert in 1899, is now in part out of harmony with known facts, while recent interpretation of previously known facts still further suggests the desirability of modification. For the *Cambrian system* Clarke and Schuchert retained essentially the classification of Walcott, which, so far as it is applicable to the facts, is a perfectly satisfactory one. The Lower Cambrian or Georgian, however, is typically developed only in the Appalachian and western provinces together with the corresponding regions of northeastern and southern Asia. The Atlantic province both of America and Europe

¹ Abstract of a paper read before the joint meeting of the New York Academy of Sciences and eastern geologists, April 6, 1908.

is known to be distinct, and the *Holmia* fauna of this province has few, if any, types in common with the *Olenellus* fauna of what might be called on the whole the Pacific province and its various intracontinental extensions. For that reason it would be well to restrict the term Georgian, and its paleontological equivalent, *Olenellus* fauna, to the Pacific province, and to adopt Matthew's term, Etcheminian (including Coldbrookian) for the Lower Cambric of the Atlantic province of America and Europe. For the corresponding fauna the term *Holmia* fauna should be adopted, since the term *Olenellus* fauna, now generally applied to this fauna without true *Olenellus*, is not only incongruous, but inevitably misleading; for it implies physiographic conditions which are now known not to have existed.* The Middle Cambric best known is that of the Atlantic province with its *Paradoxides* fauna. For this, the recognized term Acadian is most appropriate. This name, used by Matthew for the lower division of his St. John group, is thus extended to include the lower half of the Johannian, or middle division of that group. It might be desirable to use a distinct name for the Middle Cambric of the Pacific (inclusive of Appalachian) province, since these provinces were perhaps even more distinct than in Lower Cambric time. The Upper Cambric was for a long time called Potsdamian. Recognizing the unsuitableness (except in a historic sense) of this name, Walcott has proposed Saratogan to replace it. Though much better than the old name, this is still extremely unsatisfactory, because at Saratoga only the upper and in many respects least characteristic portion of the series is known. It is doubtful if the Saratoga section represents more than the Tremadoc division of the European Cambro-Ordovician transition; and aside from *Dicellocephalus*, its trilobite fauna scarcely represents the Upper Cambric.

*It should be noted that the North Scottish occurrence of the *Olenellus* fauna is clearly distinct from the Atlantic province, as repeatedly pointed out by Geikie. It probably belongs to an Arctic extension of the Pacific province.

On the Atlantic coast, the upper Johannian and the greater part of the Bretonian of Matthew's St. John group represents a typical Upper Cambric series in close harmony with that of Europe, with which it shows a striking paleontologic correspondence. The best development is on the island of Cape Breton, where its thickness approaches a thousand feet, if it does not exceed that, and where it includes the characteristic faunal zones of Europe. The upper part of the Bretonian of Matthew includes basal Ordovician beds, the line between this and the Cambric being generally drawn at the summit of the zone with *Asaphellus homfrayi*, the equivalent of the Tremadoc. This section forms a better standard for the Upper Cambric than any other known in America, and the name *Bretonian* would be most appropriate for it. Its meaning would have to be extended so as to include the upper part of the Johannian of Matthew, which term would then be discarded, while the beds above the Tremadoc horizon should be separated from it. This readjustment would not be very different from that which makes Acadian in its wider sense include the lower half of the Johannian, in addition to the Acadian in its narrower lithologic sense. Since the provinces of the Upper Cambric were less distinct, one name would suffice, but that should be Bretonian or some other equally appropriate name, rather than Saratogan or Potsdamian.

The Ordovician system has undergone a variety of classifications. At present the one generally accepted includes the Beekmantown and Chazy in the Lower, as Canadian; the Black River and Trenton in the Middle, as Mohawkian; and the remainder as Cincinnati or Upper Ordovician. This classification is out of harmony with stratigraphic and paleontologic facts. Stratigraphically, the Canadian represents some five thousand feet of calcareous strata (where developed to a maximum), while the Mohawkian includes scarcely six hundred feet. The Cincinnati as now understood is also less than a thousand feet thick, and is in part a phase of the Upper Mohawkian. The Canadian includes two distinct faunas, while the faunas

of the Mohawkian and Cincinnati are essentially a unit.

In the Mohawk Valley less than five hundred feet of Beekmantown occur, but in the southern Appalachians, from central Pennsylvania south, its thickness is 2,500 feet or more. This, as has been shown by myself³ and worked out in detail by Berkey,⁴ represents a regressional movement of the sea, begun in Lower Beekmantown time and continued throughout; so that the full measure of the depositional series is found only in the non-emerged areas of the Appalachian trough. Northward and westward from this the higher beds fail progressively, the series in central United States being complicated by the desert sands now constituting the St. Peter sandstone. Though it began before the Upper Cambrian transgression movement was fully spent, the greater part of Beekmantown sedimentation was accomplished during a period of emergence of the North American continent.

The Chazy, represented only by its higher beds, the Lowville, in the Mohawk Valley, is nearly 2,500 feet thick in central Pennsylvania, and has a similar thickness in the Appalachians southward. From the region of its greatest thickness, which is also the region of maximum development of the Beekmantown, the Chazy thins northward and westward by failure of its lower members and progressive overlap of its higher. Except in the region of non-emergence, *i. e.*, the Appalachian trough from central Pennsylvania southward, it rests disconformably upon the Beekmantown, the hiatus between the two constantly increasing northward and westward. When present, the St. Peter sandstone marks the plane of this disconformity, though its thickness is no measure of the magnitude of the hiatus. The Chazy thus represents a transgression series, pronounced in its occurrence over most of North America, but of limited extent in the type region in the St. Lawrence embayment.

³ SCIENCE, N. S., Vol. XXII., pp. 528-535, October 27, 1905, and *Bull. Geol. Soc. Am.*, Vol. 17, p. 616, 1906.

⁴ *Bull. Geol. Soc. Am.*, Vol. 17, pp. 229-250, 1906.

The Black River and Trenton limestones mark the continuance of the transgressive movement. The maximum thickness of the Trenton is less than a thousand feet, and in most places in the east it is partly replaced by the Utica shales. Thus in western New York the limestone referred to Trenton is over 950 feet thick, and the succeeding shales are probably Lorraine with little Utica. Eastward the Utica or black shale phase begins earlier, the higher limestones being replaced by the lower shales. Thus in the type region near Utica the limestone is in the neighborhood of 300 feet thick, and the Utica shale is 700 feet. Still further east, near Amsterdam, the limestone has become reduced to 87 feet, while the shale has increased to over a thousand feet. Northward the limestone increases again to nearly 600 feet in the Montreal region, while the thickness of the shale diminishes. In central Pennsylvania about 700 feet of limestone and 600 feet of shale occur, but in southern Pennsylvania Stose has found that the Trenton is almost entirely replaced by the Utica phase of shale, of which there are almost 1,000 feet of strata. These shales are succeeded by the Eden formation, which in the Cincinnati region rests on Trenton limestone. It thus appears that Trenton limestone and Utica shale represent different lithic and corresponding faunal phases of the same period of sedimentation.

During the succeeding Lower Cincinnati period an extensive retreatal, followed by a readvance movement of the interior North American sea, occurred. As a result, in the marginal portions of this sea, as in the Rocky Mountains, late Richmond rests on early Trenton or earlier beds. In the Appalachian region, extensive continental deposits marked the closing stages of this period, while in the Taconic and Acadian regions, folding was in progress.

As already intimated, three faunas are found in the American Ordovician: (1) that of the Beekmantown; (2) that of the Chazy; (3) that of the remainder of the series. The Black River fauna is in a measure transi-

tional, and may be classed with either Trenton or Chazy. These faunas and their distinctness in their calcareous as well as graptolitic phases, are well known. The last of these faunas, the Trenton-Cincinnati fauna, is of almost worldwide distribution, characterizing the foreign Upper Ordovician.

For purposes of intercontinental correlation, the graptolites are most satisfactorily employed. The world over, *Tetragraptus* and *Phyllograptus* characterize the lowest Ordovician, while *Didymograptus bifidus* further represents the highest part of this lower division. In England, the Arenig rocks include these graptolite zones, and on the continent of Europe and in Australia, etc., this Arenigian division or lower Ordovician is marked by the same graptolites. In America the shales carrying these graptolites are now regarded as of Beekmantown age, and the correlation of Beekmantown with Arenig is generally accepted. Frech, indeed, draws the line somewhat lower, making the Beekmantown (Califerous) the equivalent of the Tremadoc and part of the Arenig only. Frech, however, draws the dividing line between the Beekmantown and Chazy below the Fort Cassin beds, so that a part of his Chazy is really Beekmantown in the accepted sense. From this it appears that Lower Ordovician in America should include the Beekmantown only, applying this term to the formation in its maximum development of 2,500 feet. The term *Beekmantownian* would, therefore, be suitable as an American equivalent of Arenigian or Lower Ordovician. The Little Falls dolomytes of the Mohawk Valley represent only the lower part of this series, a similar horizon being probably represented by Cushing's "Potsdam" and Theresa formations of north-western New York. Such a classification would end the Lower Ordovician with the termination of the great retreatal movement of the sea, which, as shown elsewhere, resulted in the almost complete emergence of the North American continent. The Middle Ordovician of North America would thus begin with, and be characterized throughout by, an equally great transgressive movement, which, with

minor oscillations, again submerged the continent nearly to the extent it had suffered before the emergence.

That the Chazy, with a maximum thickness of 2,500 feet, makes an adequate representation of the Middle Ordovician can hardly be questioned. Its fauna is distinct, though not without its relationships to both preceding and succeeding faunas. In fact, the Upper Stones River phase of the fauna is so closely related to the Black River fauna that the horizon of the latter is regarded by some as more probably belonging to the Chazy. The Stones River and Lowville faunas seem to be facies faunas of the Chazy, rather than definite indices of the subdivisions of this fauna. Thus while in general the Stones River seems to be a late phase of the Chazy, succeeding the Champlain phase of the Chazy, throughout the interior, the order seems to be reversed in the South Mountain area of Pennsylvania and adjoining districts, where Stose found the Upper Shenandoah to contain a Stones River fauna followed by a Chazy-Black River fauna (Chambersburg limestone). Unless there is an error here, the Stones River fauna and typical Chazy fauna (i. e., that of the St. Lawrence embayment) must be considered as contemporaneous. From what has already been said of the relationships of Trenton and Utica deposition, the former must be classed with the Upper Ordovician. This is further shown by the faunal unity of these formations, many of the most characteristic brachiopods, bryozoa, mollusks and trilobites making their first appearance in the Trenton and continuing through the Cincinnati beds. These types, as already noted, are of wide distribution and are characteristic only of the Upper Ordovician or Caradocian of Europe and elsewhere, and more especially of the higher zones of this division.

The dividing line between Middle and Upper Ordovician is drawn in Europe above the zone of *Cænograptus gracilis*. This graptolite characterizes the Normanskill zone of America, which lies below the Trenton limestone in the Hudson Valley and probably represents Black River horizon if not late Chazy. Ac-

cepting the former equivalency, the dividing line between Middle and Upper Ordovician should be drawn at the summit of the Black River. This is where Frech draws it, throwing the Trenton limestone into the Upper Ordovician. In this I believe he is correct, though I am not fully prepared to class the Black River with the lower horizon. Dana's tentative correlation of American and British Ordovician strata parallels Arenig and Beckmantown, Llandeilo and Chazy, Bala-Caradoc and Trenton, and the lower Llandovery and Utica-Hudson. The lower Llandovery is now referred to the base of the Silurian; the "Hudson" (Lorraine-Richmond) together with the Utica-Trenton thus being referable to the Caradocian.

For the American Middle Ordovician the term *Chazyan* is here proposed. The old term Canadian would as a result become of no further significance. For the Upper Ordovician the term *Trentonian* may serve, since Trenton deposition covers at least one half this division. Moreover, the name Trenton Period was used by Dana for Trenton limestone and later divisions. *Nashvillean* would perhaps be a better name, if it is a fact that the Nashville group of Safford covers both Trenton and later Ordovician formations. *Cincinnatian* is definitely in use for Eden to Richmond inclusive, and though its meaning might be extended to include Trenton limestone, the fact that it is in general use for the higher beds might lead to confusion. The term Mohawkian would, of course, fall into disuse.

In the Appalachian region, extensive fans of continental deposits were formed during late Ordovician and early Silurian time.* In southern Pennsylvania these comprise the basal white beds, generally referred to in the literature as "Oneida," and for which the name *Tyrone* is proposed, from a locality in Pennsylvania where they are typically shown; the middle red beds or Juniata, often called red Medina; and the upper white or Tuscarora, commonly called white Medina. (The Green Pond conglomerates and Longwood shales,

and their equivalents in the Delaware and Schuylkill gaps, are not referred to here. They belong in the Salina or Middle Silurian division.) In western New York, the Juniata is represented by the Queenston shales of the present author (red Medina shales of most authors), and the Tuscarora in part by Medina. The Siluro-Ordovician dividing line falls approximately between these two, i. e., between the Juniata and Tuscarora, or the Bays and Clinch, their southern equivalents. Fossils in the Juniata and Bays (included where the river-laid beds dipped into the sea) indicate their late Ordovician (Upper Lorraine) age.

The *Silurian* has been discussed in a previous communication (January 6, 1908, *SCIENCE*, N. S., Vol. XXVII., pp. 622-23, April 17, 1908), and will be more fully treated in the forthcoming article already referred to. The essential points to be noted are: (1) That the Oswegan of Clarke and Schuchert is now known to be in part Ordovician and in part Salinan. (2) That the Silurian begins with the Medina sandstone (exclusive of Queenston shales) of western New York, which has a thickness of about 100 feet (Upper Medina of authors generally) and contains a fairly abundant fauna of Silurian age, most nearly related to the Clinton. (3) That the Clinton of the type section in eastern New York includes apparently part of the higher Niagaran beds of western New York. (4) That the pre-"Clinton" Silurian beds of the interior (Cape Girardeau beds; Alexandrian beds of T. E. Savage) are to be classed with the Lower Silurian, for which the term *Niagaran*, used by Dana for all these, is to be restored. (5) That the Middle Silurian is represented only in the interior of North America by the non-marine Salina, including the Green Pond-Shawangunk and Longwood beds. (6) That the Monroe formation or *Monroan* of Michigan, Ohio and Canada constitutes the true Upper Silurian, the Cayugan of New York (exclusive of the Salina) representing only the uppermost portion of the Monroe series.

Expressed in tabular form, the classifications here proposed are as follows:

* These will be fully discussed in a forthcoming paper by the author.

SILURIO OR ONTARIO.	Upper Silurio or <i>Monroan</i> (900-1,000 ft.)	<p>Upper Monroe (including Manlius, Rondout, Cobleskill and Bertie of New York).</p> <p>Middle Monroe (Sylvania sandstone, only known representative). Partly marked by pronounced hiatus.</p> <p>Lower Monroe (including water limes of Ohio, marine "Salina" of Maryland).</p>
	Middle Silurio or <i>Salinan</i> (1,000 ft.)	<p>Represented by the non-marine Salina sediments only in North America so far as known (including Green Pond and Shawangunk conglomerates and the red Longwood shales).</p>
	Lower Silurio or <i>Niagaran</i> (1,000 ft.)	<p>Guelph.</p> <p>Lockport.</p> <p>Rochester.</p> <p>Clinton. (Limestones and shales of western New York; Medina sandstone, including Oneida conglomerate, Tuscarora sandstone of Pennsylvania and Maryland and Clinch sandstone of Tennessee.)</p> <p>Cape Girardeau or Alexandrian (a possible equivalent of some of the Clinton divisions given above).</p>
ORDOVICIC OR CHAMPLAINIC.	Upper Ordovician or <i>Trentonian</i> (or Cincinnati, <i>sens. lat.</i> , or Nashvillean) (1,000-1,500 ft.)	<p>Richmond.</p> <p>Lorraine (including non-marine sediments; i. e., Oswego and Queenston sandstones and shales of New York, etc., Tyrone and Juniata conglomerates and sandstones of Pennsylvania; Bays sandstone of Tennessee).</p> <p>Eden formation (probably in part represented by Tyrone conglomerate).</p> <p>Utica—Trenton series.</p>
	Middle Ordovician or <i>Chazyan</i> (2,500 ft.)	<p>Black River (including Normanskill shales).</p> <p>Chazy limestone series of Lake Champlain region, and local facies, such as Lowville, Pamela, Stones River, Chambersburg beds, etc.</p>
	Lower Ordovician or <i>Beekmantownian</i> (2,500 ft.)	<p>Beekmantown limestones and dolomytes, of Lake Champlain, Deepkill and Levis shales; various local subdivisions, as Little Falls dolomite and probably the so-called "Potsdam" and Theresa formation of north-west Adirondack region.</p>
CAMBRIC OR TACONIC.	Upper Cambrio or <i>Bretonian</i>	<p>Upper part of the St. John group of the Acadian provinces and New Foundland (including Potsdamian and Saratogan as upper members, equivalent approximately to Tremadoc).</p>
	Middle Cambrio or <i>Acadian</i>	<p>Paradoxides and Protolenus beds of Atlantic province and equivalent beds of Pacific province and Appalachian embayment.</p>
	Lower Cambrio or <i>Etcheminian</i> or <i>Georgian</i>	<p>Etcheminian shales (including Coldbrookian) of Atlantic province (Holmia fauna).</p> <p>Georgia lutytes and arenites, limestones and dolomytes of Pacific-Appalachian province (Olenellus fauna).</p>

AMADEUS W. GRAHAM

RESEARCH WORK IN CHEMISTRY AT THE
UNIVERSITY OF ILLINOIS

On the evening of January 18 the Sigma Xi of the University of Illinois, held an open meeting in the chemical laboratory for the purpose of exhibiting the apparatus and methods used in research work in that department at the university.

In connection with the exhibit the following list of researches now in progress at the university was prepared. A part of these researches are conducted in the department of physiology, and a part in connection with the agricultural experiment station.

Physical Chemistry and Electrochemistry: DR. WASHBURN and DR. LACY.

E. W. Washburn: New determination of the electrochemical equivalent. Simple method for deriving thermodynamic equations.

D. A. MacInnes: Freezing point, electrical conductivity and viscosity of solutions of caesium nitrate and lithium chloride.

O. C. Stanger: Heat of dilution of cane sugar solution.

Grinnell Jones: Negative coefficient of expansion of silver iodide.

G. McP. Smith: Reversible metallic displacements in aqueous solutions.

H. C. Bennett: Electrolytic preparation of alkali and alkali earth amalgams.

Inorganic Chemistry: DR. BALKE, DR. HOLMES, DR. SMITH, DR. ISHAM, DR. JONES.

C. W. Balke: Atomic weight of tantalum.

L. H. Almy: Double fluoride of columbium and tantalum.

J. T. Nuttall: Double fluorides containing thallium and aniline.

J. E. Egan: Rare earths.

G. McP. Smith: Substituted ammonium amalgams. Determination of the density of gases by diffusion.

Helen Isham: Ferrates.

Mabel Gridley: Compounds containing hydroxylamine of crystallization.

W. B. Holmes, W. E. Knapp: Boiler water reactions.

C. E. Millar: Determination of cadmium.

V. R. Ross: Action of hydrochloric acid on manganese dioxide.

W. G. Eckhardt: Use of hydrofluoric acid in soil analysis.

Organic Chemistry: PROFESSOR CURTISS, PROFESSOR NOYES.

R. S. Curtiss: Derivatives of malonic acid and 1,3 diketones.

J. A. Kostalek: Nitrogenous acid derivatives of ethyl malonate.

F. Grace Spencer: Tartronic ester derivatives.

F. K. Strachan: Action of haloid acids on ethyl oxomalonate.

H. S. Hill: Alcohol condensations with ethyl oxomalonate.

J. J. Miller: Action of nitrous anhydride on 1,3-diketones.

G. T. Davis: Acyl peroxides.

W. A. Noyes: Molecular rearrangements in the camphor series.

C. G. Derick: Laurolene.

E. E. Gorsline: Camphononic acid.

Luther Knight: Isocamphoric acid.

Laboratory of Physiological Chemistry: PROFESSOR GRINDLEY.

H. S. Grindley, J. W. MacNeal, F. W. Gill: Effect of saltpeter in meat on metabolism.

H. S. Grindley, A. D. Emmett: Influence of different quantities of feeding stuffs on the metabolism of steers.

F. W. Gill, S. G. Allison, S. R. Wreath: Determination of sulphur.

F. W. Gill, J. B. Peterson: Determination of phosphorus.

R. M. Kibbe, A. F. Wussow: Determination of urea.

F. W. Gill, H. W. Hachmeister: Occurrence and distribution of nitrates in foods, feces and urines.

Physiological Chemistry: PROFESSOR HAWK.

H. A. Mattill: Heat of combustion of the hair of different races.

H. A. Mattill: Methylphenylosazones of levulose and glucose.

C. C. Fowler: Influence of copious water drinking on gastric digestion.

P. E. Howe, H. A. Mattill: Variations in the morphological constituents of the blood and in the "nitrogen partition" of the urine of dogs as influenced by fasting.

DR. PETERS.

Opal Burres: The diastatic enzyme of *Paramoecium* in relation to the killing concentration of copper sulphate.

H. A. Mattill: The diastatic enzyme of ripening meat.

H. W. Stewart: The absorption and partial purification of catalase from liver.

Opal Burres: A chemical and physiological study of some enzymes and toxins from *B. pyocyaneus*.

O. C. Stanger: The action of light, of oxidizing and of reducing agents upon a purified catalase.

J. H. Brown: The nature and action of the glycolytic enzyme of autolyzing muscle.

R. D. Glasgow: The extraction and properties of lipase from insects.

Industrial Chemistry: PROFESSOR PARR, DR. MEARS.

Brainerd Mears: Gas calorimeter.

D. L. Weatherhead: Asphalts.

W. F. Wheeler: Weathering of coal.

J. M. Lindgren: Boiler water.

F. W. Bliss: Occluded gases in coal. Determination of water by the phase rule.

T. R. Ernest, W. S. Williams: Sand-lime brick, and artificial silicates.

E. C. Hull: Distillation of coal at low temperatures.

R. F. Hammer: Ammonia from nitrogenous waste.

W. F. Wheeler: Calorimetric studies.

F. W. Kressman: Spontaneous combustion of coal.

Water Survey: PROFESSOR BARTOW.

Softening of the water supply of Champaign and Urbana. Clarification of cistern water. Character of water from shallow wells in cities. Municipal water supplies.

L. I. Birdsall: Action of coagulants on Lake Michigan water.

W. C. Marti: Boiler water treatment.

G. A. Van Brunt: Treatment of water with bleaching powder.

Agricultural Chemistry: PROFESSOR HOPKINS.

L. H. Smith, C. H. Myers: Breeding of corn and other crops to improve the chemical composition.

J. E. Readhimer, W. G. Eckhardt, O. F. Fisher, E. Van Alstine, J. P. Aumer, J. B. Park, Gertrud Niederman: Investigation of factors of fertility for Illinois soils, including work on experiment fields in various parts of the state and also pot experiments.

Robert Stewart: Quantitative relationships of carbon, nitrogen and phosphorus in soils.

L. H. Smith, W. B. Gernert: Transmission of the characters in corn with respect to the chemical composition of the kernel.

SOCIETIES AND ACADEMIES

THE WASHINGTON ACADEMY OF SCIENCES

The annual meeting of the Washington Academy of Sciences was held at the Cosmos Club, Washington, D. C., on Thursday, January 21, 1909.

President Walcott and about thirty members were present.

After receiving and approving the reports of the secretaries, treasurer and editor for the year just closed, the following officers were elected for the ensuing year:

President—C. D. Walcott.

Vice-presidents:

Anthropological Society—Walter Hough.

Archeological Society—Mitchell Carroll.

Biological Society—T. S. Palmer.

Botanical Society—J. N. Rose.

Chemical Society—H. W. Wiley.

Engineers Society—D. S. Carll.

Entomological Society—A. D. Hopkins.

Foresters Society—Gifford Pinchot.

Geographic Society—Willis L. Moore.

Geological Society—A. H. Brooks.

Historical Society—J. D. Morgan.

Medical Society—E. A. Balloch.

Philosophical Society—C. K. Wead.

Managers—1910: Geo. M. Kober, F. V. Coville, Bailey Willis. 1911: L. O. Howard, O. H. Tittmann, B. W. Evermann. 1912: L. A. Bauer, C. H. Merriam, C. F. Marvin.

At the close of the year the statistics of membership were as follows:

Patrons	7
Honorary members	1
Life members	1
Resident members	173
Non-resident members	157
Total	339

The non-resident members are geographically distributed as follows: California, 18; Canada, 4; Colorado, 1; Connecticut, 10; District of Columbia, 3; England, 1; Illinois, 7; Indiana, 5; Iowa, 2; Maryland, 8; Massachusetts, 24; Michigan, 1; Minnesota, 4; Missouri, 5; Nebraska, 1; New Hampshire, 3; New Jersey, 4; New York, 23; North Carolina, 1; Ohio, 4; Pennsylvania, 13; Philippines, 1; Rhode Island, 2; Tennessee, 1; Texas, 1; Virginia, 3; West Virginia, 1; Wisconsin, 4.

During the year 1908 the academy published Volume X. of its *Proceedings*, which contained 248 pages, 2 plates and 12 figures.

On the evening of February 1 Professor Albrecht Penck, of Berlin, delivered before the Washington Academy of Sciences an illustrated lecture on "The Antiquity of Man." Professor Penck kindly furnished the following abstract:

"The antiquity of man dates far back beyond all historical record. It is a purely geological question which must be treated by means of geological observation. It has been known for quite a long time that in western Europe man existed during the glacial epoch. The French geologists and anthropologists, however, who maintained this, assumed only one glacial epoch, while we know to-day that the great ice age consisted of different glacial times separated from one another by interglacial times. The traces of the various glacial epochs consist of moraines of different geological and morphological age, and there is a very strong similarity between the Wisconsin, Illinoian and Kansan moraines of North America and the Würm-, Riss- and Mindel-moraines in the circumference of the Alps, and the Günz-moraines which can be compared with the pre-Kansan moraines of North America. The traces of the interglacial periods consist of deposits with a fauna or flora which is not reconcilable with glacial conditions. The glacial conditions are determined by a lowering of the snow-line of three to four thousand feet below the snow-line of to-day as can be shown by the evolution of old glaciers, while there are indications in the Alps, judging from the corresponding flora, that the snow-line of interglacial times lay about one thousand feet higher than to-day.

"The traces of paleolithic man are found generally outside of the morainic deposits of central Europe, but there are some places where we find those traces above the moraines even of the last glacial epoch, of the Würm or Wisconsin. These are the very well-known stations of Magdalénien near Schaffhausen in Switzerland, of the Schweizersbild and the Kessler Loch. Surely man existed here after the retreat of the ice, but the accompanying fauna is still a glacial one. Man existed here just after the maximum of the last glacial epoch. We have abundant evidence of the existence of man during the beginning of the last glacial epoch as indicated by many paleolithic implements found in the loess deposits, especially those of the valley of the Danube and the valley of the Rhine, which all belong to the Solutrén.

"Of the greatest importance is the occurrence of human relics in the cavern of the Wildkirchli on Mt. Säntis in Switzerland. Here Mr. Bächler discovered, at a height of nearly five thousand feet, together with the relics of one thousand cave

bears, several hundred paleolithic instruments of Moustérien type. As we know that the Moustérien is older than the Solutrén and Magdalénien, and since it is quite impossible that man existed here during the glacial epoch, we have to deal here with traces of an interglacial man who had already appeared in the Alps, and this conclusion is corroborated by the fact that the cavern of the Wildkirchli exists in a region which overlooked the old glacier of the Rhine and the local glaciers of the Säntis, so that it was protected against glacial erosion. Probably during the last ice age the whole cavern was filled up with ice, so that the formation of the loam in the cavern ceased and no deposit was forming during the whole glaciation.

"The excavations made by order of the Prince of Monaco in the caverns near Mentone proved indeed that man existed there during the last interglacial epoch, for we find in the Grotto of the Prince beneath the cavern deposits of the glacial fauna, such deposits as an interglacial fauna contain: human skeletons and the implements of the Moustérien type. At other places, especially in France, the Moustérien implements are found together with a glacial fauna. All these localities lie outside of the Riss glaciation, and they are never met with in the realm of the old moraines, as for example, the Magdalénien. We, therefore, must believe that the Moustérien with the cold fauna is contemporaneous with the Riss ice age.

"Quite recently Mr. Hauser has discovered at Le Moustiers a human skeleton, the skull of which is of Neanderthal type, such as has been also found at Spy and Krapina. The recently discovered human jaw of Heidelberg described by Schoetensack belongs evidently to an older interglacial epoch, probably to that very long time between the Mindel and Riss ice ages, where we have also to place the Chelléen implements. Thus we have full evidence that man existed already before the Riss or Illinoian glaciation. Now it can be shown that the time elapsed since the last glaciation is far shorter than the time between the last and the glaciation before the last, between the Würm and Riss ice age. This interglacial time, however, is again far shorter than that long interval between the Mindel and Riss ice age. If, therefore, we have some reasons to believe that the time since the last glaciation was at least twenty thousand years, we must believe that the Heidelberg man dates back about two hundred thousand years.

"Far older are those coliths found in Belgium and in southeast England. They belong to the early Pleistocene epoch. And indeed we must

expect to find here implements made by early man or his predecessor, but the question is if his predecessor already belongs to the genus *Homo* or to the anthropoid apes. When we discover that the recently extinct natives of Tasmania manufactured eoliths of the same kind as those found in the old Pleistocene gravels of Belgium and England, in the upper Miocene of central France and the upper Oligocene of Belgium, we feel inclined to believe that those implements may not be regarded as *human* artefacts but as having been made by a predecessor of man. Indeed those oldest eoliths occur in a group of anthropoid mammals the genera of which are totally extinct, and it would be very surprising to find that only the genus *Homo* remained unchanged while all other genera developed."

Dr. Merriam remarked upon the Moustérien skull, suggesting that it appeared to be the skull of a child; and called attention to the remarkable differences between the Heidelberg jaw and that of man to-day, a difference so great as to indicate that the Heidelberg jaw may not belong to the genus *Homo*.

Mr. Willis inquired for the evidence that the eoliths found in Tertiary formations were actually shaped by hand and Professor Penck responded by pointing out their peculiar form, one part being shaped as if to hold in the hand and the other part a sharp edge or series of points for cutting. Such eoliths have been found dulled, as if used by man or his ancestor.

Dr. Hough remarked that as man is the only animal that has ever used fire, he desired to know whether or not traces of fire had been found at the various European localities with the other evidences of man, and Dr. Penck replied that traces of fire were found constantly with other evidences as far back as the Moustérien skeleton. No trace of fire was found with the Chelléen implements because they are alluvial and none could be preserved in such deposits.

Dr. Frank Baker called attention to the controversy that had arisen regarding certain prehistoric remains, particularly the jaw of La Nautette. It had been held that the eminences for attachment of the muscles of the tongue upon that jaw were so slight as to indicate that the animal to which the jaw belonged resembled apes in lacking the faculty of speech. Judging from the figures of the Heidelberg jaw displayed on the screen, these eminences were particularly well marked in that specimen, which would argue a special use of the tongue either for speech or for some allied function.

Mr. Spillman referred to the teeth of the Moustérien skull as being like those of a child.

J. S. DILLER,
Recording Secretary

THE AMERICAN CHEMICAL SOCIETY
NEW YORK SECTION

THE fifth regular meeting of the session of 1908-9 was held at the Chemists' Club on February 5.

The chairman, Dr. L. H. Baekeland, presented the results of an investigation which has occupied his attention for some years under the title, "Bakelite: its Synthesis, Constitution and Industrial Application."

Bakelite is a polymer of an oxybenzoyl-alcohol-methylene-glycol-anhydride having the formula $n(C_{10}H_6O_4)$. It is produced by the condensation of seven molecules of a phenolic body with one of formaldehyde. The pure substance is a hard, odorless, transparent mass resembling amber. It is insoluble in all solvents and extremely inert, resisting the action of strong chemicals and high temperatures. In its final form, Bakelite is not a plastic and would have few uses had it not been found possible to control the reaction by which it is formed and prepare intermediate condensation products. These may be incorporated with filling materials such as asbestos and wood pulp, molded into useful forms and finally hardened by the combined action of heat and pressure. The uses of Bakelite are being studied in more than forty different industries with excellent results; for example, in electricity it may be used for insulating devices and impregnating the coils of dynamos; in mechanics for bearings; in chemistry for lining wooden and metal tanks and protecting apparatus; in manufactures for making pool balls, pipe bits and buttons.

Dr. Baekeland's paper will appear later in full in the *Journal of Industrial and Engineering Chemistry*.

The other papers presented were:

M. A. Rosanoff, A. B. Lamb and E. E. Breithaut: "A New Method of Determining the Partial Vapor Pressure of Binary Mixtures."

D. D. Jackson and W. A. Horton: "Experiments on the Putrescibility Test for Sewage and Sewage Effluents."

S. A. Tucker, W. A. Alexander and H. K. Hudson: "The Relative Efficiency of the Arc and Resistance Furnace for the Manufacture of Calcium Carbide."

FROM a constructive point of view, the existing college represents for the most part tendencies rather than design. It has in the main simply come to be what it now is. True, the gardeners have pruned a bit here and tied up a bit there. But the hedge has been trampled down, and things have been suffered to grow with less regard to the demands of the market than to the fertility of the soil. Provisionally, this style of farming has its advantages. It at least instructs us as to what will grow under given conditions. There comes a time, however, when indiscriminate abundance and variety must submit to a process of evaluation; when wasteful natural productivity is no longer best adapted to meet the demonstrated or calculable needs of a well-defined social organization; when, in a word, we must ask which part of the crop has value, and to what end. This necessity is, I take it, reflected in the question proposed for to-day's discussion.

Two things have happened in higher education during the last thirty years: in the richer and more progressive sections of the country the traditional one-curriculum college has been practically demolished; the graduate school has been evolved. The demolition of the old-fashioned college helped, of course, to make a clearing for the graduate school, and the concurrent growth of the graduate school

¹MSB, intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

¹An address given before the Section of Education at the Baltimore meeting of the American Association for the Advancement of Science.

hastened the completer demolition of the college. But educationally the two phenomena are not the same. We can neither appreciate nor escape our present plight, until we hold them in thought at arm's length from each other—in thought, for summary geographical sundering of the one from the other is not at this moment advocated, I believe, by anybody.

I say the old college has gone to pieces. But it has not simply gone to pieces, leaving a dust heap to mark its site. It has perished as perishes a frontier town, in the very process of conversion into a modern city. The significant aspects that meet the eye are not so much the evidences of dissolution as the preparations for a new, more commodious and more substantial structure. The college has increased its resources, it has undertaken to serve a far wider range of social activities by frankly conceding the culture-value and dignity of science and of the useful arts. This extension of scope saved it from extinction, at the same time that it procured for the college a far more vital function than it had previously discharged. The historian of our educational history will, I believe, speak of this successful transformation as the great educational achievement of the generation following the Civil War—an achievement destined to be permanently associated with the name and leadership of President Eliot.

On the other hand, from the standpoint of the incoming generation, it is fair to regard the college situation as still undetermined. I have used the word "preparations" advisedly. The college has in hand the elements out of which effective schools may some day actually be made. But they have not been made as yet. Except in the realm of technical education, the college is still almost wholly unorganized. The question inevitably arises whether educational organization at the college

level must be limited to the technical field; further, whether it is only the technical instinct that discloses itself during adolescence; finally, whether other types once made out may not be equally amenable to organized educational treatment. In a previous discussion¹ I excluded the technical school, not because it ought to be severed from the college, but because criticism aimed at collegiate chaos does not lie as against the technical departments. I hope now to show that, so far from having no bearing on the academic situation, the technical school, whatever its present defects, is really highly suggestive. The college recognizes the technical motive, stimulates and rewards its expression by providing for it adequate and continuous discipline. It has no fear of wrecking a youth who expects to be an engineer by encouraging him to know his mind at eighteen; in other cases, however, it keeps hands off for fear of doing violence to what is deepest in social and individual activity. Hence, the college outside the technical field now almost entirely avoids definite formulation on the educational side. Once a minimum of content and a maximum of organization, it is now a maximum of content and a minimum of organization.

It is as though a great clearing had been made to which stone and timber, lime and sand have been hauled in large quantities. But neither architect nor builder appears. Meanwhile the neighborhood children play at building with the material. They pile up rambling inconsequential structures that quickly collapse into as many shapeless separate heaps. The brick and stone are college courses; the separate heaps represent individual curricula; the children building without eventual purpose are college students; and the utter absence

¹ "The American College," p. 48, etc.

of connective mortar or controlling design is the elective system!

The college development of the last thirty years amounts, then, from our present standpoint, to educational opportunity rather than educational achievement. Meanwhile the graduate school can not be characterized in similarly negative terms. Its activity in accumulating and refining material represents positive achievement of the highest order. But not college achievement; a serious pedagogical misconception is involved in embracing college and graduate work in a single appreciation. Research is essentially a post-collegiate affair. Not, of course, the research-spirit: that belongs to every stage of modern education; it has its place in the elementary school, in the secondary school, in the college, in each of which the pupil gets some of his motive power from an active curiosity, a distinct tension or problem-sense, far more efficacious in disclosing and disciplining power than a didactic routine smacking strongly of authority. When I urge that the college is not the place for research, I do not say that it is not the place for the research spirit; I do not say that originality, initiative, native reaction on the student's part, are not to be sought after. What I mean is that these essential qualities are not developed only in searching or researching for new material; they are just as readily evoked in situations that are old, provided only the situations be real, pressing, vital and in so far novel to the boy. Thus the research spirit freely stimulated through childhood and adolescence provides background and basis adequate both to suggest and to support genuine problems. Lacking this, problems are given to, not felt out by, the student. This distinction can be made with infinite advantage to both college and graduate school. Failure to perceive it has led to the premature forcing of

research and research workers upon the college, as if only thus college studies could be vitalized. Of course, if it is true that research can alone keep teachers from outright ossification, haste must be made to introduce it into the secondary and primary schools, where it is equally important to have teachers who can bend without breaking. The fact is, however, that some men have totally dried up while researching; that others keep their effervescent sparkle without research by cultivating an open and ready responsiveness to novelty, regardless of whether it issue out of the narrow limits of the university laboratory or out of the great laboratory of human life itself. It is absurd to ignore the stimulus of modern life at large and to emphasize exclusively the aspects of activity represented by the academic workshop. All the live men are not laboratory investigators; nor are all the investigators keenly alive. Now then, research in the eulogistic and narrow sense concerns itself altogether with the employment by mature intellects of a powerful technique for the express purpose of increasing or refining knowledge. For this sort of thing the graduate school is the proper place; and the graduate school in its brief history has contributed substantially to increase our intellectual store of precious metal.

The college was enabled at a critical juncture to import generously from the newly established and highly productive laboratories and libraries; but the very bounteousness and suddenness of the enrichment operated to hinder the growth of definite conceptions of college function. The lack of adjustment, which our topic confesses, originates just here. The concern of the college is with students, not with stuff. Adjusting the college to life means the pedagogic assimilation and organization of this accumulated and accumulating material; bringing it to bear

in essential social and individual functions. It does not mean pushing the boundaries of science a little farther into the still unexplored regions of the north, but rather employing our scientific resources to make life itself more highly intelligible and satisfying; it means not delving more deeply for such fragments of historic detail as may have hitherto escaped detection, but making our historic and ethical knowledge tell, in comprehending and rationally modifying what now is. This is a different thing from merely mining for additional facts; a different thing from just getting to know the stock on hand. The business of the college is human and disciplinary, formative and cultural. Its important relations are to *society*, not to *knowledge*, as such; relations *through* knowledge, rather than *to* knowledge. Knowledge is its tool, not its end. From the college point of view, knowledge is just so much raw material, and the more refined, abstract, logically separate and complete, the rawer it is; the more it needs reconstruction, digestion, recombination in ways suggested from the boy's side by genetic psychology, from the social side by the forms into which at a given epoch common activities have been differentiated.

Surely this is what "adjustment" means. When we talk of adjusting the college to life, we mean in plain language working out a concrete educational scheme which will adjust each individual boy to the concrete social situation. Of course this is not all we mean. Education is something more than a mere adjustment. It is also concerned with developing demands on the child's part calculated to upset the existing adjustment. The child must be, in a word, fitted to play his part; straightway that part and the actual social order including it offend his awakened rationality. It is then equally the busi-

ness of education to fit him to assist in further progress. The college is in this respect but the culmination of, not fundamentally disconnected from, the elementary and high schools. Throughout all these stages of growth and adjustment, education contemplates an actual emergency—a here and now, made up of ascertainable factors. Such a situation can be either superficially or profoundly analyzed in the effort to reach its essential constituents. The elementary school analyzes it largely from the physical and impulsive sides. The high school penetrates farther on the civic and ethical sides; on the individual side, it distinctly seeks to exploit the boy in the hope, among other things, of disclosing the particular way in which he can himself function in society. On both sides the college must proceed still further. Individual differentiation on vocational lines comes in the college period still more sharply to the front; simultaneously, it is all the more important, if the college is to make good the alleged breadth of its discipline, to open the boy's eyes to what is characteristic and significant in the life that is to be the background, basis and standard of all his subsequent activity. An educated man is, in a word, a citizen of the world, of his time, of his nation, just as really as he is a member of a craft, a profession, or a union. And he needs specific training for the former as for the latter.

The common backbone of an adequate educational scheme is thus suggested. Practically the best that the college can now count on in this matter from previous education is a fair knowledge of the facts of our own and English history and some appreciation of the workings and ideals of our own institutions. Hence the college is at once confronted with the necessity of working out a common discipline which will give all students alike a wider outlook,

a deeper grasp of facts, a keener sense of their significance. Unless educated men meet upon such common basis and interest, education, instead of bringing our resources to bear most effectively on the conscious purpose of society, tends to detach disciplined minds from each other and from a common object. The high school comes too soon to do this; the professional school too late. A vague sense of this obligation the college still betrays in clinging to catchwords like "broad," "liberal," "training for citizenship," "training for character." But one can lay one's hands on nothing definite in the curriculum that is actually calculated to make for breadth, liberality or citizenship. The subjects are not there; the treatment is distinctly hostile. At best, special, not general, individual, not basic, needs dictate the composition of the student's course of study. Now, without a curriculum organized and presented with this clearly conceived object in view, what reason is there to believe that the student possesses either the intelligence or the impulse to construct for himself a discipline from which he will emerge with the necessary comprehension and disposition? He lacks the requisite knowledge, purpose and intelligence; and as a democratic society aims to realize not instinctive, but rational ideals, it would be strange indeed if every boy who had read Caesar and studied algebra already felt the sure ethical and speculative solicitude which it is precisely the task and difficulty of education to develop within him. That is a matter which a society endeavoring to realize conscious ideals through its own corporate action does not leave to the discretion of the individual boy. Of course, it will prize the will or instinct, if he chances to possess it; it will set about creating it, however, if he doesn't. Such training is in the highest sense formative, cultural, human. It suggests a field of

college pedagogy which will be opened up for settlement and cultivation when the outposts of research are withdrawn to their own proper territory, just as a secondary school pedagogy will become possible when the college vacates its mechanical and unintelligent control. Contemplating this broad general outlook or basis for all college students, regardless of the special activities which as individuals they may pursue, Professor Mann has recently sketched a college treatment of science that falls in completely with this view:

It would seem, then, that for the normal non-specialist the present instruction in laboratory science, with its wealth of exactness and technical detail, is a misfit. What is needed for these general students in college is a discussion of the bearing of science on the history and present forms of social and economic life, with no laboratory work of the present sort, rather than the customary re-hash of a subject-matter from which the juice should already have been pressed. In other words, the college course in science should try to give to the student who seeks breadth and culture a new and enlarged view of the value and the bearing of science in human life, rather than to fill him with a more detailed and more highly specialized mass of information, which, at his age, ordinarily interests him but little and arouses his enthusiasm even less.

Looked at from this point of view, a course in science in college would be very different from any now given there. If the science were physics, the proposed course might begin with a discussion of the steam engine. Attention should be given to the social and economic changes conditioned by or closely connected with the development of the steam engine, and of its application to manufacture and transportation. When the steam engine was finished, electricity might be taken up in the same way. The electric telegraph and the dynamo and the telephone have certainly affected economic and social life in a powerful way, and played an important part in bringing about present conditions. The entire subject of electricity could easily be brought, if desired, into a discussion of the subject from this point of view. Practical appliances like those just mentioned should not, however, receive all of the attention of the class. The achievements in pure science must not be neglected. Thus the Copernican system of astron-

omy has certainly had a tremendous effect on our intellectual and spiritual life. The important points are briefly these: (1) For the specialist in science or in engineering, college laboratory work of the right sort is an essential part of his professional training. (2) For the non-technical or general student, college laboratory work is neither essential nor desirable; the emphasis in this case should be laid on the services of science in developing and maintaining intellectual, social and economic life.

Thus the college will have made the first step towards a definite adjustment to the conditions of life, when it has worked out a fundamental, common basis which takes up the essential and significant factors of actually extant activities. It has next beyond this a specific duty in reference to each individual, the duty of preparing him for his particular function in just this same society. The particular function of the student must then at this moment be decided: on native lines, if possible, but decided, in any event. As to this I shall have a word to say presently. Just now I point out that the valid scope of election can extend only to such choice of individual function. That choice once made, it is the business of the college to devise the educational procedure that will give it effect. The task is made generally possible of achievement by the fact that modern society has already been differentiated into certain typical forms, a process rapidly going further. The tendency is not without dangers, which would, however, be partly combated by the general cultural procedure already suggested, and partly otherwise. To ascertain what the types in question are and what the lines of training adapted to each, the college must again recur to the existing social situation, in order to discover the forms in which individual energy plays and to work out for each its appropriate pedagogical expression. It is needless to attempt a list of these types now. That again is a task

for the college pedagogy yet unborn. Local as well as general conditions here come into play; not impossibly the attempt to recognize and to develop such types may lead to a differentiation among colleges, each of which will then perhaps no longer seek to be all things to everybody. For purposes of illustration, having already touched upon engineering, I confine myself now to the well-defined professions of law and medicine and to trade. In each of these we must organize a curriculum which will constitute an effective preparation for a subsequent training that, once begun, can not afford to concern itself with preliminary matters, and that will also relate the career in question to social life at large. In general, instruction on these lines must be liberally and not just technically conceived. Take the case of medicine. The college will, within its limits, train broadly when, free from any immediate technical responsibility such as exists in the professional school itself, it presents every subject philosophically as well as technically. The student of biology, physics and chemistry is thus on the technical side preparing for the study of medicine; meanwhile the bearing of modern scientific methods and discoveries on the whole trend of social speculation and activity may be simultaneously made clear to him. If we exclude the distractions that are now largely through administrative timidity suffered to consume much of his time and energy, and organize his instruction, as to both substance and method, with a clear notion of what we are driving at, the college years amply suffice for the thorough two-sided treatment of the scientific basis of subsequent medical study.

The argument holds equally in reference to law. I submit that a careful analysis of the function of the lawyer in modern society will suggest a very definite preparation for his career, though the col-

lege now puts no particular pressure upon the future law student to find himself. The lawyer nowadays is two things. He is obviously a practitioner. For this line of activity he can doubtless be admirably prepared by a sharp and severe technical drill in the law school. So far, he is only the clerk of his clients. But he is in reality much more than this. He is the main agent in adapting the great institutional arrangements of society to its progressive movement. As judge and legislator, it is the lawyer who interprets, embodies and guides deep social and ethical currents. True enough, few lawyers as yet appreciate and deliberately prepare themselves to exercise this function; hence their resistant, anti-social, obstructive bias. But the college that seeks to train a race of intelligent broad-gauge men will embrace the opportunity to produce through a profound study of ethical and industrial forces and developments a race of lawyers whose later technical acquisitions and point of view will be conditioned by a large consciousness of their constructive social responsibility. The lawyer is in large measure obstetrician to the future: whether the birth will be painful or gentle depends in no small degree on the skill, intelligence and large-mindedness with which our lawyers frame, apply and judge our laws. We live in a legal and institutional framework that was built to protect us against dangers, many of which no longer exist. Meanwhile totally different emergencies have arisen. The question to be solved through and, to a considerable extent, by our lawyers, is whether these institutions can be adapted to new conditions without interruption of historic continuity. To appreciate their problem, to get in possession of the data bearing on it, the lawyer of the future must rest his specific legal training on an adequate grasp of the tendencies, perplexities and

rational ideals that are seeking to utter themselves. Once more, such training must be had in the college, if it is to be had anywhere. I repeat, the high school comes too early; the professional school is too busy and too late. And the training in question must be worked out *for* the boy, not *by* him. That such preliminary training would be in the truest sense liberal as opposed to the immediately technical, vocational or professional, can, I think, not be seriously disputed.

An analogous course of reasoning applies to business. It is perfectly possible even now to organize a course of study calculated to prepare a youth to engage efficiently in commerce and to take broad and intelligent views of the part that at this moment commerce plays in promoting national development and in realizing rational ideals. This, I conceive, would be a liberal, cultural treatment of the trade-motive. That such an attempt would not now be premature, Harvard has proved by organizing a school of business administration. Unfortunately, it is a graduate school, thus illustrating once more the tendency to empty the college of all definite content and responsibility. A student intending to embark in trade is compelled, before he can enjoy the opportunities of the graduate school of business administration, to spend four years in college, doing nothing in particular, before he can at twenty-three get tardy leave to spend two more years preparing to be an intelligent business man. The analogy followed in making the school a graduate school is that of law and medicine: a mistaken analogy, as it seems to me. The student who gets his degree in law or medicine is a lawyer or a doctor. The student who passes through the graduate school of business is not a business man. He has accomplished in reference to business exactly what the preliminary training in biology

and chemistry has done for the intending physician, and analogy would therefore require that the business school become a differentiated college type analogous to the differentiated college types looking forward to law and medicine. The catalogue explains the graduate constitution of the school on the grounds that students must be mature and that the work is specialized and technical. I confess that to me it appears neither more difficult nor more highly specialized than many of the courses provided for undergraduates. Harvard opens to ordinary undergraduates courses in statistics, the economics of transportation, banking and exchange, labor problems, corporation economics, public finance, taxation, railroad practise, principles of accounting, principles of law governing industrial relations, not to mention others like the theory of crises, to which undergraduates may be admitted. Is it possible to make the slightest distinction on the score of difficulty or technicality between the courses just mentioned as open to undergraduates and the following, constituting the business courses, from which they are excluded: economic resources of the United States, industrial organization, banking, railroad operation, municipal business? Neither in the necessary maturity of the students nor in the special or technical character of the topics is there the least difference. The real consideration lies here: the college is so disorganized and usually so averse to definite conception of function and to maintenance of standards adequate to future use, that whatever is serious, organized and definitely purposeful tends to become post-collegiate. Had the college been given to organization and serious standards, the graduate school of business would have made an additional college type resting upon the same general basis as the legal and medical types; and the subjects com-

posing it would be pursued and presented in both their technical and their liberal bearings.

The proposed organization of the curriculum on the basis of differentiated social types differs essentially from the so-called group system. The group system presents combinations on departmental lines: Latin and Greek, biology and chemistry, mathematics and physics. The two subjects forming a group belong, as a rule, closely together, and they enter into combination as linguistic or scientific entities detached as far as may be from practical or social concern—which detachment is, by the way, accounted an advantage from the cultural standpoint. The logical or departmental integrity of the subject becomes thus as prominent in the college as in the graduate school, where conditions and aims are so very different. To my thinking, the college thus goes far towards defeating its own cultural purpose. I do not pretend, of course, that the culture value and the scientific value of biology, for example, are two separable elements; my meaning will be clear from an educational point of view when I say that the cultural importance of biology to the college student comes out when, in addition to his mastery of biological science as such, its history, its applications, its influence on the development of thought, have been explicitly brought forward; when, in other words, the vocational bearing and the social significance of the vocation in question supervene upon the strictly scientific study. Our present college methods of handling science suffer not from too much, but from too little vocational and professional insight. Of course, the vocational handling of biology may readily be just as narrow as the scientific. But an intelligent treatment, such as the college is the place and has the time for, so far from confining the student to mean ends, will open his eyes to

the social and philosophical significance of the activity to which his college studies lead and upon which he will presently embark. Such a treatment the group system, dealing with subjects as subjects, does not essay.

It is, in other words, quite clear that under modern conditions whatever breadth of intelligence the boy attains—and this is, I take it, mainly what is meant by culture—has to be got *through* his activities—social and individual—and not as *against* them or in their despite. This is the fact on which the elective system is based, whether in the unorganized form now in common use or in the organized form which I am urging. So far, a common argument protects both; the diversity of college opportunity corresponds to the diversity of social need. It can not be arbitrarily abridged or reduced. Selection is inevitable; let it be made as economically and effectively as possible. At this point the cultivated man becomes apprehensive. He fears that election dictated by personal bent or professional need may dwarf the student, mind and soul. To some extent this danger will have been frustrated by the common organic basis which, as has been pointed out, should lie below all individual selection whatsoever. Beyond this, the elected studies must be so handled as to avoid the reproach of narrowness. It is in any event inevitable that a rightly elected college course will presage the student's practical destiny. The same factors determine both—capacity or bent, if he has it—otherwise, opportunity, environment. In the common run of cases, unless the student is a Dr. Jekyll in college and a Mr. Hyde out of it, the two phases will be harmonious. The business and glory of the college are then, not stupidly to ignore or vainly to resist the vocational factor, but deliberately to develop in advance its cultural meaning and

possibilities. The disappointment with which we now survey results is to be ascribed to our failure to do this very thing.

The main difficulty in putting into operation the policy I have suggested relates to finding proper teachers. I must touch this vital consideration very briefly. The colleges are apt to attribute their pedagogic shortcomings to lack of teachers; I attribute the lack of teachers to the pedagogic shortcomings of the colleges. Our colleges have done little or nothing to develop teachers; they have emphasized, rewarded and competed for specialists. The college function has been lost in the eagerness to encourage research. Now it has at length been found that the two functions are not identical; that men trained to do the one can not equally well do the other. That certain individuals may profitably do both, that the college and the graduate school are closely related, that they may often best flourish in one institution; all this may be admitted, while still maintaining that the crying need of our academic life is for the creation on the part of college authorities of conditions and ideals that will permit a race of college teachers to grow up and to survive.

A college organized along the lines above laid down could, as it seems to me, claim a certain degree of adjustment to modern life, taken as a whole and equally in reference to its constituent activities. I am not unmindful of the fact that such college organization presupposes a different type of secondary school from what we now possess. This opens up a subject I can not now discuss; but I will say this, that an intelligent secondary school pedagogy, such as is already struggling against college pressure to assert itself, may quite conceivably, among other things, succeed in disclosing the youth's essential affinities, dealing with him, as it would, freely dur-

ing the most characteristic and expansive epoch of his life. Despite conditions extremely unfavorable to decisive choice, statistics, roughly compiled for me, seem to indicate that perhaps seventy-five per cent. of the members of the first-year law classes at Columbia and Harvard knew while in college that they would study law afterwards. This would, I think, justify the college in the very definite procedure that I have advocated. In the case of the engineer, the college even now requires an early decision, followed by continuous hard work; it is difficult to see why either the decision or the hard work should be restricted to prospective engineers.

In the last event, supposing that no bent is revealed—and it seems to me absurd to treat the matter as if every schoolboy has some biologically grounded fitness for some one particular calling—I am inclined to believe that it is wasteful and demoralizing to encourage dispersion by the unregulated opportunity to modify, retract and get lost. The college would do better to treat the vagrant with the wholesome rigor that society employs without compunction in the case of the working boy who, in default of a distinct gift or bent, is arbitrarily apprenticed at sixteen. Would it be better if he were maintained as a parasite until such time as he really concluded at his leisure whether he preferred to be a carpenter or a mason?

Several causes have combined to prolong the chaotic condition of the college. In the first place, college administrators have been terrorized or hypnotized by the term culture. For a long while it was identified with a perfunctory knowledge of Latin and Greek grammar and a few books of Cæsar, Xenophon, and perhaps Virgil, and was sharply antithetic to anything that could possibly be of any use. This is mere rubbish. There is possible a liberal or cultural or philosophic treat-

ment of a man's primary practical concern; and the college which does not occupy itself with such interests in just that spirit has lost an important reason for existence. All these antitheses between vocation and culture, science and culture, business and culture, have got to be resolved by a breadth of treatment which absorbs both. Treated in a vital human spirit, every interest of human faculty is culture. The classics may be—and usually are—sterilized so as largely to lose their culture-value; and science may be humanized and thus gain it.

An equally disastrous bogey has been freedom. We are forbidden to adjust the college to existing social conditions through definite organization, subject to revision as society develops, on the ground that the boy can be disciplined to freedom only through freedom. This absolutely negative conception of liberty, having been thoroughly discredited in politics, economics, philosophy, has trekked over into the educational field, after having been shown the door everywhere else. Now in education, as in economics, liberty interpreted as the absence of organization is of provisional service only in relatively brief periods following the abolition of purely arbitrary restrictions. Under such conditions, it allows repressed, ignored, unknown tendencies to disclose themselves; it permits the real factors in a situation to be ascertained, to the end that, once known, they may within limits be controlled in reference to deliberate design. Our real freedom is thus enhanced, not destroyed. We triumph over limitation only by submitting to it. Mr. Santayana says:

The only artists who can show great originality are those trained in distinct and established schools. It is only in recent times that discoveries in science have been frequent, because natural science until lately possessed no settled method, and no considerable fund of acquired truths. So too in political society, statesman-

ship is made possible by traditional policies, generalship by military institutions, great financiers by established commerce.

To the same effect, President Pritchett has lately said, speaking of education:

Organization which is wise, which respects fundamental tendencies and forces, which separates incongruous phases of activity, may not only add to the efficiency of educational effort, but may offer a larger measure of freedom than can be hoped for in chaotic and unrelated efforts to accomplish the same ends.

Even in the home of academic freedom the force of these words can be illustrated. For the honor degrees at Harvard are conferred only after the completion of certain correlated and combined courses, selected *for*, not *by*, the student. Does not this fact plainly indicate that where seriousness begins, there some form of enforced coordination begins also?

The objection to negative freedom does not, however, drive us back to positive, but arbitrary restriction. Still less can the difficulty be met by the illogical Yale-Princeton compromise, according to which the student gets practically two years of each—the freshman and sophomore years devoted to conventional restrictions, the junior and senior years to negative freedom, qualified though it is by the inevitable mechanical inconveniences of the time-table and a few departmental sequences. In considering only the two alternatives here in question or their combination in equal consecutive parts, the colleges overlook altogether the organic character of a genuine educational solution.

I should like briefly to touch another essential point. It is absolutely futile to talk of adjusting to life an institution of such easy virtue as our present college. Perhaps its demoralization of standards simply expresses the fact that, as it serves no particular educational purpose, it is immaterial whether the student takes the

thing seriously or not. But a college organized on the lines I have suggested has no other choice but seriousness. We still bear traces of our English collegiate origin in the familiar twaddle about the college as a sort of gentlemen factory—a gentleman being a youth free of the suspicion of thoroughness or definite purpose. Now, I grant that as long as a single required course was forced upon every student, it would have been absurd to require the same sort of performance of every one. The prospective don could fairly be held to a standard not applicable to the future country squire. But the elective system—organized or unorganized—knocks the props from under the gentleman, or citizen—as he is sometimes called. It proposes to do for each student what he needs. It is thus illogical not to require a high grade of excellence of all alike. Ineffective performance can no longer be excused on the ground of the irrelevancy of the task. The tolerant attitude of the college towards every form of individual capacity and social opportunity compels a serious treatment on both individual and social grounds.

The fact that the college has so frequently demoralized rather than stimulated occasionally leads men who have been developed by the struggle for opportunity to look upon mere abundance of opportunity as itself disastrous. Our strong man of the last generation had to fight for his chance; and that was the making of him. A costly discipline, to be sure, but not altogether a bad one. To-day, far better opportunities than he fought for are easy and accessible. The struggle of our children must then be not *for* opportunities, but *within* them. The college offers the chance, it makes every concession to individual capacity and disposition. It must demand, therefore, a genuine performance at every point. To make opportunities

abundant and standards low is thoroughly immoral.

CARNEGIE FOUNDATION FOR THE
ADVANCEMENT OF TEACHING

A DANGER ARISING FROM THE POPULARIZATION OF THE COLLEGE¹

I WISH to speak of a danger which threatens the American college as the result of changes in the work of the college and in its environment whose joint effect may be summed up in the phrase, "the popularization of the college."

The history of the American college begins about the close of the first third of the seventeenth century, Harvard College having been founded in 1637. The traditional college curriculum, which was not radically changed till about the middle of the nineteenth century, was largely due to the intellectual conditions of the seventeenth century. When Harvard College was founded, there was very little to be studied, beyond the rudiments of a common English education, excepting Latin, Greek and Hebrew and a little mathematics. At that very time Descartes was shaping the outlines of the method of coordinates in geometry, but the world had still to wait half a century for the invention of the calculus. A half-century was to elapse before Newton's great discovery of gravitation gave unity to the conception of the universe. Almost a century and a half was to pass away before the discoveries of Priestley and Lavoisier created the science of chemistry. The "*Systema Naturæ*" of Linnæus did not appear until Harvard College was already a century old. A century and a half was to elapse before geology and paleontology took

shape under the hands of Hutton and Cuvier. It was almost a century and a half before Adam Smith's "*Wealth of Nations*" laid the foundations of the modern study of economics. It was more than half a century before Locke's "*Essay on the Human Understanding*" opened the discussions of the modern period of philosophy. More than two centuries were to elapse before the study of language took on a scientific form in Grimm's "*Geschichte der deutschen Sprache*." Two editions had already appeared of the collected plays of Shakespeare, but as yet no one dreamed of English literature as standing on a par with the great classic literatures as an object of study; and still less would it have occurred to any English-speaking educator to think of the literature of any other modern language as a worthy object of study. The ancient languages and a little mathematics formed about all the educational material that was accessible in the seventeenth century, and it was nothing strange that the curriculum developed in the environment of that age survived for a considerable time after the environment had changed. But the old curriculum has now become thoroughly extinct. The new branches of learning which have developed in the last three centuries have come to take a dominant position in the education of youth, as in the thought of manhood. The wealth of educational material at present available is vastly larger than any one can deal with in the brief years of the college course. Everywhere the fixed curriculum has given place to the elective system. With the recognition that the field of learning is so large that no one can secure even an introduction to all departments of it in the college course, the elective system has become a practical necessity. From the vast variety of attractive and useful studies each student is rightly left to select, in

¹ Address given before the Section of Education of the American Association for the Advancement of Science.

large measure, according to his own idiosyncrasies, tastes and professional plans.

With this change in the studies of the college course has been associated a change in the constituency of the college. In earlier days the fixed curriculum of the college was supposed, rightly or wrongly, to be adapted to furnish the best substratum for the subsequent professional training of men who were dedicated to the three pursuits known as the "learned professions"—the ministry, the law and medicine. The members of these professions formed a sharply defined intellectual aristocracy. Membership in that aristocracy was, in large degree, hereditary. The members of these professions constituted what Dr. Holmes has felicitously called "the Brahmin caste" in the American society of earlier days. For those boys who were not destined for the learned professions, and for all girls, the training of the common schools in the three R's was supposed to be all-sufficient. To-day there is no such Brahmin caste. The aristocratic constitution of society has changed to one which is intellectually, as well as politically, democratic. The academies and high schools teach the rudiments of the new learning to boys and girls who have no aspiration for any specially learned professions, but who are to do the common work of men and women in society. In the changes which have passed over society new professions have developed which rival the old learned professions in their demand for advanced intellectual training. The work of the teacher has been evolved into a distinct profession, instead of being merely an incidental and temporary employment for persons who were ultimately to pass into other walks of life. The applications of science in the various useful arts have created a demand for advanced intellectual training on the part of multitudes of

men who are destined not to lives of scholastic seclusion, but to lives whose business is with the concrete realities of the material world. There is no sharp distinction between a learned class and an unlearned mass; there is rather an indefinite gradation from the most educated to the least educated members of the community. Now that the sciences of nature, the modern languages and literatures, history, economics and sociology have assumed a dominant position in the college course, the college attracts to itself a much wider and more varied constituency. Not alone the devotees of the ancient learned professions, but multitudes of those who are going into the variety of pursuits embraced under the general name of business, throng to the college, and find there instruction and training which will fit them for larger views of their own calling and for broader service as citizens. The college community has become relatively heterogeneous.

Precisely herein lies the danger to which I have thought it worth while to call your attention. In the olden time it was assumed that every student in college was dedicated to a distinctively intellectual pursuit. His life was to be a scholarly life. Hence a scholarly aim, more or less definitely conceived and more or less consistently maintained, during the college course, was expected on the part of all. Now a large share of college students are looking to something very different from a life of learned seclusion. They are to be in the busy world of affairs; they are to develop the material wealth of the community. The careers for which they are intending to fit themselves will demand intellectual vigor and, in many cases, a considerable degree of special knowledge; but they are not careers that would naturally be called scholarly. Hence there comes a pressure exerted upon college faculties to tolerate a lower standard in the scholastic

work of the college, on the ground that a large part of the young men enrolled in the college have no intention of giving themselves to scholarly pursuits, and can not be reasonably expected to have a scholarly spirit. The trouble is not simply that some men do not study. That was always the fact. No system ever fulfills its own ideal; and in the old days, when it was supposed that all students were preparing to be scholars, the supposition was very far from being exactly in accordance with the reality. But then the men who did not study knew and confessed that they ought to study. Now it is gravely asserted in influential quarters that many students in college ought not to study to any very great extent, and ought not to be expected to study; that, as they are never intending to be scholars, there is no need of their being particularly scholarly even during their school life. Precisely on this ground, then, there is a pressure not only on the part of friends of particular students, but also on the part of influential alumni and alumni clubs and associations, to admit men who are unprepared, to tolerate men who are neglecting their work, and to graduate men who have accomplished very little in the line of study. Especially is such a pressure exerted in behalf of men who are distinguishing themselves as athletes during their school and college life, and in behalf of men who are likely to come into possession of considerable money. In urging the claims of such men for peculiarly lenient treatment in college, it is seriously maintained that it is a good thing for men who are going into business, or any other pursuit not distinctly scholastic in character, to go to college with no intention of doing any considerable amount of studying, and to be graduated without having done any considerable amount of studying. It is urged that, if they spend the four years

essentially in the avocations of student life—athletics, social events, amusements, college politics—and, in the occasional intervals of leisure which these exhausting avocations may afford, study enough to pass examinations and to be graduated *speciali gratia*, they will yet absorb from the general atmosphere of the college an influence in the direction of increasing breadth of view and higher ideals in life which will be worth the cost in time and money. I do not believe that this view finds much support among college faculties; but I do believe that continual pressure in this direction actually tends to secure the admission of men with lower standards of preparation, and the graduation of men with lower standards of scholarly achievement, than would otherwise be tolerated. The whole position seems to me radically wrong. The business of a student is to study; and for the individual student to spend the four years in the vocation, and to devote the bulk of his continual and systematic neglect of his time and mental energy to the avocations of student activities, is essentially demoralizing. He leaves college with a weakened sense of responsibility, and a conscience which has grown increasingly tolerant of self-indulgence. He has suffered a distinct loss in those elements of strength of character which qualify a man for noble achievement in any department of human life.

If the evil effect were confined to the individuals directly concerned, it would be less serious than it actually is; for a class of men who are in college not to study but for other purposes, exerts an influence upon the college body in the direction of degradation of scholarship and deterioration of character. Especially strong is this evil influence if the men concerned possess athletic ability, wealth, attractive manners and amiable social

qualities which result in their being recognized as social leaders.

Besides the general pressure in the direction of leniency as regards the standards of admission and graduation, the notion that it is desirable to fill up our colleges with a class of students who have no serious ambition to study, has created a tendency to the more liberal admission of students on special courses. I think there would be substantially unanimous agreement among college faculties in the belief that there ought to be some persons admitted as special students. The opportunities of instruction which a college affords can, without any detriment to those who are taking regular courses leading to a degree, be afforded to certain classes of students whose age, financial condition or other circumstances may make it entirely impracticable for them to complete the college curriculum. Teachers in high schools and similar institutions can often get leave of absence for a year, or for a part of a year, and improve the time in earnest study in college in a department in which they are teaching, and in which they have already attained a proficiency which fits them to take advanced work in college. Men and women engaged in various professional or technical pursuits may, in like manner, gain very much by special courses in the colleges in lines of study connected with their work. In such cases, though the persons may not have completed any of the prescribed courses of preparation for college, they are yet fitted by maturity of age, definiteness of purpose and thorough training along some lines of study or intellectual work, to take up the studies of some departments with great advantage to themselves, and with positive benefit rather than loss to the college. It is sometimes justifiable to admit as special students those who wish to take a somewhat general course of study similar to

that which would be required for the bachelor's degree, but whose preliminary schooling has been irregular, and who have not covered exactly any prescribed course for admission to college, though the aggregate of training which they have received may be equal in amount or even superior to that which would fit them for admission to college. This is the case sometimes with those who have commenced professional or technical studies and subsequently awake to the necessity of gaining more of general education. In some cases it is legitimate to admit as special students candidates who are expected eventually to get into a regular course of study and take a degree. But to smuggle into college under the name of special students candidates who have simply made a failure of the preparatory course, through lack of ability or through lack of industry, is an evasion which can not be practised without demoralization of the college. But there are probably very few administrative officers or committees having charge of the admission of students to college, to whom the outside pressure for the practise of such evasions has not come to be a familiar experience.

The principle must be explicitly affirmed, and consistently and at times sternly maintained in practise, that, however widely diversified may be the college course under the operation of the elective system, and however cordially men and women preparing for careers widely different from those involved in the traditional learned professions may be welcomed to college, only those students are welcome who come to study—who feel the genuine vocation of the student, and in whose plans for the years of college life the avocations of student life are to be distinctly subordinate to the great vocation. Within limits by no means narrow, they may study what they please; they may shape their

course very largely with reference to the non-scholastic pursuits which await them after leaving college; if they do not want to study Greek, they may study French or German or Spanish; they may study applications of science, as well as pure science; if they do not want to study philosophy or advanced mathematics, they may study the labor problem, or banking and currency, or commercial geography and commercial law: only let it be understood that whatever they profess to study they must really study. In a college, as in a railroad station, there is no room for loafers.

WILLIAM NORTH RICE

THE PALEONTOLOGICAL SOCIETY

For some years there has been a growing desire among paleontologists for a society in which students of all branches of paleontology can unite for the promotion of their common interests. Such an organization has now been effected as a section of the Geological Society of America under the name of "The Paleontological Society."

The preliminary correspondence which was begun by Professor Charles Schuchert, of Yale University, early last year, was inspired by the successful meeting of the American Society of Vertebrate Paleontologists in New Haven. This correspondence developed the fact that nearly 60 paleontologists are ready to unite in a general society, and of these, 34 attended the first meeting for organization in Baltimore on December 30, 1908. At this meeting an Executive Committee, consisting of Charles Schuchert, F. B. Loomis, S. W. Williston, David White, H. F. Osborn and T. W. Stanton, was appointed with full power to act for the society.

On February 13, 1909, the Executive Committee met with a special committee of the Geological Society of America in the American Museum of Natural History, New York City, and made a satisfactory adjustment of the relations between the two societies. The committee also prepared a constitution and by-laws and elected the following board of

officers for the Paleontological Society to serve the remainder of this year:

President—John M. Clarke.

First Vice-president—John C. Merriam.

Second Vice-president—Timothy W. Stanton.

Third Vice-president—David White.

Treasurer—William D. Matthew.

Secretary—Herdman F. Cleland.

Editor—Charles R. Eastman.

It is expected that all the paleontologists of North America will be enrolled in the membership of the new society before next winter, when its first regular meeting will be held with a full program of papers.

T. W. STANTON

ENGINEERS OF WISCONSIN FORM STATE SOCIETY

THE organization of the Engineering Society of Wisconsin was completed at the first meeting, held at the University of Wisconsin February 24-26, at which some 150 city engineers, general managers of power and traction companies, contracting engineers, superintendents of water and light plants, mechanical and civil engineers, and superintendents of highway construction were present and became charter members.

The officers elected were: *President*, Dean F. E. Turneure, College of Engineering, University of Wisconsin; *Vice-president*, City Engineer McClelland Dodge, of Appleton; *Trustees* for two years, B. F. Lyons, assistant general manager of the Beloit Gas and Electric Co., and E. P. Worden, mechanical engineer of the Prescott Steam Pump Co., Milwaukee; *Trustees* for one year, E. Gonzenbach, of the Sheboygan Electric Light and Power Co., and City Engineer E. R. Banks, of Superior. These, as executive board, will elect the secretary later.

The new organization will hold annual meetings hereafter for the purpose of bringing together the engineers from all parts of the state interested in the solution of such problems as arise in connection with municipal plants, large construction work, bridge, forest and water-power questions, and light and power production. A wide range of subjects

was included in the program for the initial meeting of the society.

At the opening session, February 24, following the address of welcome by President Charles R. Van Hise, was a presentation of the scope of the highway work of the State Geological Survey, by W. O. Hotchkiss, highway engineer for the survey. A. R. Hirst, also of the state highway department, spoke on the use of tar, oils and emulsions on macadam and earth roads. The discussion on pavements was led by McClelland Dodge, city engineer of Appleton, and participated in by P. H. Connelly, city engineer of Racine; W. G. Kirchoffer, consulting engineer, Madison, and others. City Engineer C. V. Kerch, of Janesville, spoke on the construction of the Court Street bridge in that city.

Interest in the discussion of the conservation of forests and water resources of Wisconsin, a subject presented by State Forester E. M. Griffith, waxed so keen that the paper on "The Water-power Resources of the State," by Professor L. S. Smith, who is engineer for both the state and national geological surveys, was postponed to the following evening. The conservation discussion was led by Senator T. W. Brazeau, and Senator E. E. Brown, Assemblyman J. R. Jones and Professor D. W. Mead also spoke on the subject.

Professor W. D. Pence, who is engineer for the Wisconsin Railroad Commission, opened the second day's program with a description of the organization of the commission's engineering staff. The new problem of standards of gas and electric service was discussed by Professor C. F. Burgess, of the department of applied electrochemistry at the university, who has done important work in enabling the state railroad commission to prescribe a standard for fuel and illuminating gas.

The electric interurban roads of Wisconsin were made the subject of an address by F. G. Simmons, superintendent of construction and maintenance of way for the Milwaukee Electric Railway and Light Company. The day circuit for small towns was discussed by Professor J. W. Shuster, and new forms of arc lamps by W. E. Wickenden, also of the elec-

trical engineering department. Dean Turneure took the members of the society through the engineering experimental laboratories, explaining the work that is being done there in many lines of research.

The second night was given to a discussion of water powers, W. G. Kirchoffer describing the water supply of the city of Marshfield, and Professor D. W. Mead the subject of hydraulic and hydroelectric power development. Papers on "The Waterproofing of Concrete," by F. M. McCulloch, city engineer of Stoughton; "Municipal Engineering in the Orient and in Porto Rico," by J. T. Hurd and Edwin Wray; "Gas Producers and Small Power Stations," by V. E. McMullen, Beloit, and C. T. Atkinson; and "Madison's Concrete Storm Sewer System," by City Engineer John F. Icke, concluded the convention program.

THE DARWIN CENTENARY

To commemorate the centenary of the birth of Charles Darwin, Professor Vines, Professor Poulton and Professor Bourne gave an "At Home" to the university in the Examination Schools, Oxford, on February 12. There was a large and distinguished gathering, including four of Charles Darwin's sons—Mr. William Darwin, Sir George Darwin, Mr. Francis Darwin and Major Leonard Darwin. Books, letters, etc., of Charles Darwin were shown by Mr. R. W. T. Günther (Magdalen), and Professor Poulton made an address on "Fifty Years of Darwinism." Sir George Darwin and Mr. Francis Darwin briefly addressed the gathering.

THE Darwin centenary was celebrated at Shrewsbury, his birthplace, under the auspices of the Shropshire Natural History Society. Dr. Cosmo Melvill presided, and Dr. Hoyle, of Manchester University, gave an address on Darwin.

THE special business of the meeting of the Academy of Natural Sciences, of Philadelphia, held February 16, was the commemoration of the centenary of the birth of Charles Darwin and of the fiftieth year of the publication of the "Origin of Species." The president, Dr. Samuel G. Dixon, spoke of the in-

fluence of the doctrines of natural selection and evolution on the development of thought and the progress of humanity. Dr. Arthur Erwin Brown, one of the vice-presidents, referred to the fact that the academy had been the first society in America to recognize the importance of Darwin's work and quoted from his letter to Lyell, of May 8, 1860, in which he says: "This morning I got a letter from the Academy of Natural Sciences of Philadelphia, announcing that I am elected a correspondent. . . . It shows that some naturalists there do not think me such a scientific profligate as many think me here." Dr. Brown also read a letter addressed by Darwin to Dr. Joseph Leidy, under date of March 4, 1860, acknowledging receipt of publications, expressing appreciation of Dr. Leidy's work and returning thanks for his support of the doctrine of natural selection. Dr. Edwin G. Conklin, also vice-president, then read a memoir of Darwin dwelling on the importance of his work in science and on the relation of the doctrine of natural selection to modern thought. A collection of Darwin's works and his letter of acknowledgment of election as correspondent of the academy were exhibited.

THE biological and botanical departments of Brown University held a meeting commemorative of the Charles Darwin Centennial on February 12. The program was:

Introductory remarks with exhibition of portraits of Darwin and his contemporaries, by A. D. Mead.

"Darwin's Relation to Theories of Heredity," by Professor W. E. Castle, of Harvard University.

"Darwin's Influence on Practical Breeding in the Work of Luther Burbank," by Dr. George H. Shull, of the Carnegie Institution, Station for Experimental Evolution.

THE State University of Iowa celebrated the Darwin Centennial by two addresses at the assembly of all colleges. Professor C. C. Nutting spoke upon the personal traits of Darwin, and Professor T. H. Macbride upon his contributions to botany. The Baconian Club devoted its evening program to the memory of Darwin and addresses were made on his contributions to zoology, botany and psychol-

ogy by Professors G. L. Houser, B. F. Shimek and C. E. Seashore, respectively.

THE Society of Arts held a meeting in commemoration of the birth of Charles Darwin at the Massachusetts Institute of Technology. Addresses were made by Professor William T. Sedgwick, of the biological department, and Professor Percival Lowell, non-resident professor of astronomy at the institute and director of the Lowell Observatory at Flagstaff, Ariz.

THE CARNEGIE FOUNDATION FOR THE ADVANCEMENT OF TEACHING

Two special recommendations have been made by the executive committee of the Carnegie Foundation to the board of trustees and, having been adopted by the board, have been incorporated in the rules of the foundation. By one of these recommendations the maximum amount of a retiring allowance is raised from \$3,000 to \$4,000, and by the other the executive committee is directed to grant a pension to the widow of a professor in an accepted institution who has been for ten years married to the professor, the pension to be one half of what the husband would have been entitled to receive. Heretofore the pensions to widows have been only permissive. They have now been raised from discretionary ones to a certain provision by the adoption of the following rule:

Any person who has been for ten years the wife of a professor either in receipt of a pension or entitled to receive one shall receive during her widowhood one half of the allowance to which her husband was entitled.

The rules for the granting of retiring allowances in force January 4, 1909, are as follows:

A normal retiring allowance is considered to be one awarded to a professor in an accepted college, university or technical school, on the ground either of age or of length of service. The term professor, as here used, is understood to include presidents, deans, professors, associate professors and assistant professors in such institutions of higher learning.

In reckoning the amount of the retiring allowance the average salary for the last five

years of active service shall be considered the active pay.

Retiring allowances shall be granted under the following rules, upon the application of the institution with which the professor is connected. Application blanks for this purpose are furnished by the foundation. The ground upon which the application is recommended, whether it is upon the basis of age or upon the basis of service, should be stated in each case.

1. *Basis of Age*.—Any person sixty-five years of age, who has had not less than fifteen years of service as a professor and who is at the time a professor in an accepted institution, shall be entitled to an annual retiring allowance, computed as follows:

(a) For an active pay of twelve hundred dollars or less, an allowance of one thousand dollars, providing no retiring allowance shall exceed ninety per cent. of the active pay.

(b) For an active pay greater than twelve hundred dollars the retiring allowance shall equal one thousand dollars, increased by fifty dollars for each one hundred dollars of active pay in excess of twelve hundred dollars.

(c) No retiring allowance shall exceed four thousand dollars.

Computed by the formula: $R = A/2 + 400$ where R = annual retiring allowance, A = active pay.

2. *Basis of Service*.—Any person who has had a service of twenty-five years as a professor, and who is at the time a professor in an accepted institution, shall be entitled to a retiring allowance computed as follows:

(a) For an active pay of twelve hundred dollars or less, a retiring allowance of eight hundred dollars, provided that no retiring allowance shall exceed eighty per cent of the active pay.

(b) For an active pay greater than twelve hundred dollars, the retiring allowance shall equal eight hundred dollars, increased by forty dollars for each one hundred dollars in excess of twelve hundred dollars.

(c) For each additional year of service above twenty-five, the retiring allowance shall be increased by one per cent. of the active pay.

(d) No retiring allowance shall exceed four thousand dollars.

Computed by the formula: $R = A/100(b + 15) + 320$ where R = retiring allowance, A = active pay and b = number of years of service.

3. Any person who has been for ten years the

wife of a professor either in receipt of a pension or entitled to receive one shall receive during her widowhood one half of the allowance to which her husband was entitled.

4. In the preceding rules, years of leave of absence are to be counted as years of service, but not exceeding one year in seven. Librarians, registrars, recorders and administrative officers of long tenure, whose salaries may be classed with those of professors and assistant professors, are considered eligible to the benefits of a retiring allowance.

5. Teachers in the professional departments of universities, whose principal work is outside the profession of teaching, are not included.

6. The benefits of the foundation shall not be available to those whose active service ceased before April 16, 1905, the date of Mr. Carnegie's original letter to the trustees.

7. In counting years of service toward a retiring allowance, it is not necessary that the whole of the service shall have been given in institutions upon the accepted list of the foundation.

8. In no case shall any allowance be paid to a teacher who continues to give the whole or part of his time to the work of teaching as a member of the instructing staff of a college or technical school.

9. The Carnegie Foundation for the Advancement of Teaching retains the power to alter these rules in such manner as experience may indicate as desirable for the benefit of the whole body of teachers.

SCIENTIFIC NOTES AND NEWS

THE Berlin Academy of Sciences has awarded its Helmholtz medal to Professor Emil Fischer, for his work on the sugars and albuminoids.

DR. FRANK D. ADAMS, dean of the faculty of applied science and professor of geology at McGill University, has been elected an honorary life member of the Institute of Mining and Metallurgy of Great Britain.

THE Royal Society of Arts has presented its Albert medal to Sir James Dewar, F.R.S., for his investigations into the liquefaction of gases and the properties of matter at low temperatures.

THE managers of the department of archeology of the University of Pennsylvania have awarded the Lucy Wharton Draxel medal, for

important work in exploration and publication, to Professor Rudolph E. Brunnov, for his work in Assyria and in the exploration of Arabia.

MR. ARTHUR HILL, regent of the University of Michigan, has made the offer to the board of regents of a bronze or marble bas-relief of President James B. Angell, in commemoration of his eightieth birthday and the valuable services which he has rendered to the university, state and nation. The monument will be placed in the new Memorial Hall.

DR. EDGAR F. SMITH, professor of chemistry and vice-provost of the University of Pennsylvania, is recovering from a somewhat serious illness.

DR. C. C. CLARK, associate statistician of the Department of Agriculture, has accepted an appointment as chief of the Bureau of General Statistics and Agricultural Information in the International Institute at Rome.

At the annual meeting of the Royal Astronomical Society on February 12 Mr. H. F. Newall, the president, extended a cordial welcome to Professor O. Backlund, director of the observatory, Pulkowa, Russia, to whom the society's gold medal had been awarded. The Jackson-Cwilt bronze medal and gift were handed to Mr. P. Melotte, of the Royal Observatory, Greenwich, in recognition of his discovery of the eighth satellite of Jupiter. Sir David Gill was elected president of the society for the coming year; Sir W. H. M. Christie and Messrs. J. W. L. Glaisher, H. F. Newall and H. H. Turner, vice-presidents; Major E. H. Hills, treasurer; Messrs. A. R. Hinks and S. A. Saunder, secretaries, and Sir W. Higgins, foreign secretary.

MR. ECKLEY BRINTON COXE, JR., founder of the Coxe archeological expedition from the University of Pennsylvania, and Dr. George B. Gordon, curator of the museum, have sailed for Egypt to join members of the expedition who are working in Nubia.

DR. J. K. SMALL, head curator of the museums and herbarium of the New York Botanical Garden, accompanied by Mr. J. J. Carter, of Pleasant Grove, Pa., has been in south

Florida for botanical exploration and collecting on the everglade keys, in continuation of his previous work in that region and his studies of the plants of the southeastern United States. Dr. J. A. Shafer, museum custodian in the garden, is in Cuba, commissioned to spend about three months collecting in the northeastern portion of that island, which has been little visited by botanists.

DR. HIRAM BINGHAM, JR., instructor in Latin-American history at Yale University, who is now in southern Peru on his South American trip of historical research, is reported to have made important discoveries of Inca remains near Abancay, Peru.

A MEETING of the Columbia Chapter of the Society of Sigma Xi was held on March 4 in Fayerweather Hall. "The Sanitary Protection of Tidal Waters" was the topic of the evening, and George A. Soper, C.E., Ph.D., president of the Metropolitan Sewerage Commission, the lecturer. The address described the harmful consequences resulting from the discharge of sewage into tidal harbors and the measures taken to prevent excessive pollution.

MR. W. H. FINLEY, assistant chief engineer of the Chicago and Northwestern Railway Company, gave a lecture before the College of Engineering of the University of Illinois on Friday, February 19 on "The Quebec Bridge Failure."

At the 658th meeting of the Society of Arts, Boston, on February 27, Professor Charles E. Lucke, of Columbia University, made an address on the subject of internal combustion engines.

PRESIDENT TAFT gave the annual Washington's Birthday oration at the University of Pennsylvania, being presented by the governor of the state. Among those on whom the doctorate of laws was conferred was Dr. Samuel G. Dixon, formerly professor in the university and now Commissioner of Health in the state of Pennsylvania.

PRESIDENT HADLEY, of Yale University, made the commemoration day address at the Johns Hopkins University on February 22, which was entitled "Two Sides of University Life."

PROFESSOR E. S. MORSE lectured at Tufts College on February 24 on "Natural Selection and its Application to the Darwinian Theory of the 'Survival of the Fittest.'"

PROFESSOR LIGHTNER WITMER, of the University of Pennsylvania, is giving this term a course of lectures on psychology to the fourth year students of the medical department.

EDWIN KATZENELLENBOGEN, Ph.D. (Leipzig), assistant physician at the Danvers Hospital for the Insane, and fellow for research in logic at Harvard University, is to give a course of lectures on psychopathology, consisting of a treatment of selected topics in abnormal psychology. These lectures, which will be open primarily to graduate students, will occupy one hour and a half weekly. In each month three of the lectures will be delivered in the Psychological Lecture Room; the remaining exercise each month will take place at the Danvers Hospital for the Insane, at Hathorne. Special attention will be given to the legal aspects of psychopathology.

THE Kaiser Wilhelm has recalled his veto of the Virchow monument design and has approved the second sketch. The monument will now be erected on the Karl Platz near the Charité.

DR. WILLIAM TILLINGHAST BULL, professor of the practise of surgery at Columbia University and one of the most prominent surgeons in New York City, died on February 22, at the age of fifty-nine years.

THE death is announced of Sir George King, F.R.S., late director of the Botanical Survey of India, aged sixty-eight and of Professor Julius Thomsen, president of the Royal Danish Society of Science, aged eighty-two.

THE "sundry civil" bill for the fiscal year 1910, as reported to the House of Representatives February 19, provides for a new building in Washington to accommodate the Geological Survey, the General Land Office, the Office of Indian Affairs and the Reclamation Service, to cost \$2,500,000, and appropriates \$100,000 for preliminary work in construction. The site named in the bill is the square bounded by E and F and Eighteenth and Nineteenth

streets, west of the building occupied by the State, War and Navy departments and about three blocks west of the White House. For twenty-five years the survey has occupied a rented building on F Street, in the heart of the business section of the city, the annual rental of which now amounts to \$34,900. This building is not fireproof and has been three times visited by destructive fires, the last one, in December, 1908, burning government property worth \$15,000. The annual rentals paid by the survey and the Reclamation Service amount to about \$43,000, and the provision made for the Indian and Land offices in the new building will permit the transfer of other bureaus, now in rented quarters, to a building owned by the government. The annual net saving accomplished will be \$51,400.

THE Yale *Daily News* has made a statistical study of the early training of the 15,142 men, sketches of whose lives appear in Appleton's *Cyclopedia of American Biography*. 5,826 of these prominent men are college trained, with the colleges, credited with over one hundred, represented in the list as follows: Harvard, 883; Yale, 713; Princeton, 319; Dartmouth, 208; Columbia, 198; Brown, 189; Union, 188; Pennsylvania, 175; Williams, 157; Bowdoin, 104; Amherst, 102. Yale's honor roll is divided among the professions as follows: clergymen, 194; lawyers, 149; educators, 83; statesmen, 55; authors, 53; doctors, 43; scientists, 38; soldiers, 37; business men, 19; journalists, 15; in government service, 14; philanthropists, 6; artists, 4; inventors, 3.

WE learn from the *Journal of the American Medical Association* that the International Bureau of Public Health was formally inaugurated at Paris on November 10, 1908, and the director and secretary were installed in office by the committee, composed of one representative from each of the countries which have agreed to support the newly created bureau. Dr. S. B. Grubbs, of the Public Health and Marine Hospital Service, was the United States delegate. The idea of having a central and international office for the purpose of gathering and distributing information concerning the graver epidemic diseases,

especially cholera, plague and yellow fever, was first presented for consideration at the international sanitary convention of Paris, in 1903, although it had been advocated for some time previously by many sanitarians, notably the late Professor Proust, of Paris. At the request of the convention of 1903, the French government undertook the task of presenting to the nations interested propositions regarding the organization of such a bureau. These propositions were submitted in a final form in August, 1907, and a conference was invited by the government of the French republic, at the instance of the Italian government. This conference was held at Rome, December 3, 1907, the delegates signing for the governments of Belgium, Brazil, Spain, the United States, the French republic, Great Britain and Ireland, Italy, the Netherlands, Portugal, Roumania, Russia, Switzerland and Egypt. It is believed that the exchange of ideas that will take place at the semi-annual gathering of the governing committee will have a beneficial effect on international sanitation. In organization the bureau resembles the permanent International Postal Bureau and the Bureau of Weights and Measures.

IN a letter to the editor of the *Yale Alumni Weekly*, in reply to a notification of his accession to the title of oldest living graduate of the university, Chester Dutton, '38, wrote recently as follows:

The position of Oldest Living Graduate is *very temporary*. About seven years ago it fell to my early neighbor & friend Mr. L. W. Cutler of Watertown Conn. (Yale 1829), who was a perfect specimen of physical manhood, as well as a man without faults and without enemies, and he held it, I think, for a few weeks.

I recall that more than seventy years ago both Prof. Silliman & Prof. Olmsted predicted many of the wonderful utilities of present day life—Both discussed photography and telegraphy and the use of electro magnetism for power as assured results, only waiting on human ingenuity for methods of production and application. The Ocean Steamer however, the Ocean Cable, & the telephone and the skyscraper—and electrical lighting were not talked of; perhaps not thought of. One problem then regarded with much concern was the future supply of light, as the *whales* were be-

coming scarce. Petroleum was peddled for *medicine* in pint bottles under the name of "rock oil from Kentucky"—Friction (or explosive) matches had come into use about 1834 or 5, 100 matches in a little box, for 25 cents. Prof. Silliman suggested the probable necessity of governments prohibiting their manufacture & sale, on account their possible use by incendiaries.

UNIVERSITY AND EDUCATIONAL NEWS

AT the exercises on February 22 in commemoration of the founding of Johns Hopkins University, which opened thirty-three years ago, it was announced that the gift of Mr. Henry Phipps, of New York, for the psychiatric clinic was considerably in excess of \$1,000,000.

A GIFT of \$200,000 to the University of Pennsylvania from an anonymous donor was announced at the exercises on Washington's birthday by provost Harrison. It will be used to establish a department of medical research. The gift was received through Dr. John H. Musser, of the faculty of medicine.

THE sons and daughters of the late Mr. and Mrs. F. C. A. Denkmann, of Rock Island, Ill., have promised to give a library building to Augustana College and Theological Seminary, Rock Island, the building to cost not less than \$100,000, and to be known as "The Denkmann Memorial Library."

By the will of Dr. Gordon W. Russell, of Hartford, class of '34, Trinity College, receives \$5,000 for the natural history department and a collection of books on that subject.

AN addition has been made to the observatory building at the University of Michigan, including a new dome 40 feet in diameter. The university is also installing a large reflecting telescope which is now approaching completion, and has been designed especially for photographic and spectroscopic work.

COMER HALL, the new engineering building of the University of Alabama, will be ready for occupancy about May 1. It is a large structure of two stories with a ground-floor space something over three quarters of an acre, and will accommodate the departments of civil, mechanical, mining and electrical

engineering and physics. The cost of the building and equipment will be \$150,000. Smith Hall, named for Professor Eugene A. Smith, of the chair of geology, is also nearing completion, and will be occupied by the departments of geology and biology. This building will cost \$100,000. An academic building, to be a duplicate of Smith Hall, will be begun in the near future.

At a session of the committee on education of the Massachusetts legislature on February 24 the establishment of a "Massachusetts College" was considered. The aim of such an institution was explained by Mr. Courtenay Crocker, Mr. Edmund D. Barbour and Professor Thomas A. Jagger, to be to carry higher education to people not in a position to seek its seats at colleges and universities, to give it at a cost which would bring it within reach of those in less than moderate circumstances, and to furnish a training which would justify the awarding of the degrees of A.B. and A.M. Mr. Barbour has offered to give \$100,000 to promote the plan.

THE trustees of Wesleyan University have voted to abolish coeducation in the institution after the class entering in the fall of 1909. It is planned, however, to establish in connection with the university a college for women.

MR. SAMUEL W. MCCALL, congressman from Massachusetts, has declined the offer of the presidency of Dartmouth College.

LORANDE LOSS WOODRUFF, Ph.D. (Columbia), has been advanced to an assistant professorship of biology in Yale University.

ASSISTANT PROFESSOR ROBERT W. HALL has been promoted to the professorship of biology at Lehigh University.

MR. LOUIS A. HERDT, associate professor of electrical engineering at McGill University, will succeed Professor Owens in the chair of electrical engineering.

THE electors to the Waynflete professorship of mineralogy at Oxford have elected Dr. Herbert Lister Bowman, M.A., D.Sc., New College, to the professorship in the place of Dr. Henry A. Miers, D.Sc., fellow of Magdalen,

who resigned this chair last October, on his election to the principalship of London University.

DISCUSSION AND CORRESPONDENCE

FOREST PRESERVATION

TO THE EDITOR OF SCIENCE: In a recent number of an engineering paper appears an editorial entitled, "How 'Concrete Lumber' Has Made Forest Preservation a Farce." The article opens with the following words:

The fast-perishing forests of America have been the theme of many a statistical lament. "Behold the loss of all this wealth, this criminal waste of natural resources!" cries the statistician, until we find ourselves almost sniffing in sympathy. Amid all this *illogical agitation* (sic) for forest preservation it is well to turn an eye toward the timber of the future "concrete lumber" as it has been aptly called, etc.

Are we to understand that engineers and contractors are willing to look forward to a concrete age, which will be independent of the waste of natural resources? The statistician tells us that the production of cement in 1890 was 325,000 barrels; in 1907 it was 52,000,000 barrels, worth \$56,000,000. Will some one tell us how many tons of coal will be required to manufacture the cement which the world will require during the present century? And then will some one go farther and estimate how many board feet of lumber are likely to be used to make the forms required for concrete construction? The organized effort which is now being made to educate the people, so that wasteful extravagance shall cease, should receive the hearty support of the engineering profession and press. The following statement of Dr. I. C. White, state geologist of West Virginia, is likely to become classic and can not be too often reprinted:

Just as sure as the sun shines and the sum of two and two is four, unless this insane riot of destruction and waste of our fuel resources which has characterized the past century shall be speedily ended, our industrial power and supremacy will, after a meteor-like existence, revert before the close of the present century to those nations

that conserve and prize at their proper value their priceless treasures of carbon.

U. S. DEPARTMENT OF AGRICULTURE

MAGNETIC ROCKS

WHILE in southern Arkansas recently, studying the northern outcrops of the oil-bearing horizons of Louisiana, I took occasion to ascertain whether the peridotite eruptions about Murfreesboro, Arkansas, were as magnetic as similar rocks in central New York. They prove to be so; hence it seems that if a somewhat detailed magnetic survey of the region thereabout were made the tens of thousands of dollars now expended in worthless options might practically all be saved. Naturally in searching for diamonds the first information desired is the whereabouts of the volcanic necks bearing the diamond dirt. Though these are covered by plateau gravel or alluvial sands and clays they can be detected as readily as the dikes in central New York can be located though under many feet of glacial till.

G. D. HARRIS,
Geologist to Louisiana

A NEW PHENOMENON IN ELECTRIC DISCHARGE

DURING last May the writer used a wire of platinum having a diameter of 0.005 cm., in some work in electric discharge around a right angle in a wire. The discharges were made non-oscillatory in character, by introducing into the circuit a couple of strips of cloth such as is used for surgical bandages. These strips, which were in multiple, connected two tumblers containing salt solution, one of which was about 20 cm. above the other.

During about three weeks of use, a system of wavelets formed along the whole length of the wire. They were very uniform in dimensions. The wave-length was 0.090 cm., and the amplitude from crest to crest was 0.015 cm. The wire was under tension of four grams weight, by means of silk threads passing over pulleys.

The writer is under the impression that the irregular bending of wires traversed by a con-

tinuous current has been observed, but is unable to find a reference to it.

FRANCIS E. NIPHER

THE DATING OF PUBLICATIONS

TO THE EDITOR OF SCIENCE: Through accident or policy, the Carnegie Institution has not dated many of its recent publications. In bibliographical citations, where dates are used to designate publications, it is difficult to dispose of papers where the time of publication is not given. Moreover, is it not desirable to date articles, to protect the writers in priority?

February 2, 1909

SCIENTIFIC BOOKS

Die Metamorphose der Insekten. Von P. DEGENER. Pp. 56. Leipzig u. Berlin, B. G. Teubner. 1909.

This little book, by one who has written several valuable articles on the development of the alimentary tract of insects, is one of the most thoughtful and suggestive of a number of recent general accounts of Hexapod metamorphosis. The author adopts the now usually accepted view, advanced by Fritz Müller in 1864, that the larvæ and pupæ of insects represent cœnogenetic adaptations, the result of a tendency, so to speak, on the part of an originally monomorphic form, to become strongly trimorphic during its ontogeny. In other words, the more specialized insects (Holometabola) have found it increasingly advantageous to assume three successive forms during their metembryonic development: the first, or larva, being devoted to alimentation and growth, and often exhibiting peculiar modifications to suit the highly specialized environment in which it lives, the third, or imago, being devoted to the reproduction and dissemination of the species, and the second, or pupa, providing for the transformation necessitated by the two other very different stages.

DeGENER's work is divided into three parts: an analysis of the organization of the larva, a consideration of the phylogeny of metamorphosis and of the significance of the pupal stage. He recognizes three kinds of larvæ:

the *imaginiform*, which occurs in the Ametabola (Heteroptera, Orthoptera) and is very similar to the imago into which it develops, the *semimaginiform*, which occurs in the Hemimetabola (Amphibiotica, some Homoptera) and is less similar to the adult, and the *true larva* of the Holometabola (Hymenoptera, Diptera, Coleoptera, Lepidoptera, etc.), which is succeeded by a quiescent pupal stage. The organs of the various larvæ are considered under the following heads:

1. Larval organs that are simpler than those of the imago but of nearly the same structure, or such as are absent in the imago but are nevertheless of a primitive character, as shown by comparison with their homologues in lower insects. Examples of such organs are the mouth-parts and antennæ of ephemeropterid larvæ, the cerci of campodeiform larvæ, non-pentamerous tarsi, etc.

2. Organs that are more or less atrophied or vestigial in both larva and imago, *e. g.*, the labium and maxillæ of *Corethra* and *Chironomus*, the larval eyes of *Corethra*, etc.

3. Organs that were first acquired by the imago but subsequently transmitted to the larva, or that have taken on the imaginal form secondarily in the larva, like the sucking mouth-parts of the Hemiptera. To this category Deegener also assigns organs which appear in the larva as primordia of imaginal structures. These he calls *secondary imaginal discs*, in contradistinction to the *primary imaginal discs* which are represented by such structures as the wing-pads of the imaginiform and semimaginiform larvæ.

4. Organs that have been acquired by the larva independently of the imago and are either completely lacking in the latter (pedes spurii, sericteries) or have been acquired by it secondarily (external gills of some Perlids, rectal gills of Odonata, etc.). Such structures are designated as *provisional organs of the first order*.

5. Organs common to both larva and imago but developing in different directions in the two instars (sucking mandibles of the larval *Hemerobius*, *Chrysopa* and *Dytiscus*; digging legs of *Oicada* larvæ). Such structures are called *provisional organs of the second order*.

6. Organs that are typical or primitive portions of the insect organization but are completely retarded in their development during larval life and remain as primordia, or imaginal discs. These are called *tertiary imaginal discs* to distinguish them from the primary and secondary imaginal discs mentioned under (8). The gonads and their ducts, especially the latter, may be included under this sixth category, but in one sense they form a category by themselves, as they are not specifically insect organs and as the gonads sometimes mature during larval or pupal life.

Deegener calls attention to the fact that none of the organs of the imago is actually lacking in the larva, but that the latter may possess organs which do not occur in the imago. He concludes from this that the true larva "must be derived from the imago and hence presupposes the existence of the imago, and that therefore this is phylogenetically older than the larva, but that the true larva is younger phylogenetically than the imaginiform young of the Epimorpha and semimaginiform young of the Hemimetabola." This conclusion and Deegener's classification of larval characters would appear in a somewhat clearer light had he not neglected to take the embryo into consideration. A single example will make this statement clear. It is well known that certain embryonic organs, such as the thoracic appendages and antennæ, are lacking, as appendages, in the vermiform, or apod larvæ of many Hymenoptera, Diptera and Coleoptera, but are present again in the imago. This fact alone proves that the vermiform larva is an extreme cœnogenetic adaptation. It also throws light on another matter which Deegener, Heymons, Berlese and a host of other writers seem not to have clearly grasped, namely, the significance of the relations of the abdominal appendages of the embryo insect to the so-called prolegs. (pedes spurii) of the larva. Deegener says of these:

I assume that the pedes spurii do not arise directly by transformation from the appendages of polypod ancestors, and hence that they are not phylogenetic recapitulations (any more than are the tracheal gills) but are to be regarded as new

formations, which, however, have not originated independently of the vestiges of the abdominal appendages. The looseness of this dependence, however, is shown in certain Noctuid caterpillars, in which some of the pairs of prolegs make their appearance during larval life and hence at a time when the abdominal appendages have completely disappeared. I can not, therefore, regard the *pedes spurii* as primary, or even as resuscitated organs, but only as secondarily adapted provisional organs.

This statement if applied to the ontogeny would involve the unwarrantable assumption that the abdominal legs of the embryo disappear in the larva. This they do in many cases as hollow ectodermal evaginations filled with mesoderm, but they persist, nevertheless, as small, flat cellular areas in the ectoderm. In other cases, there is abundant evidence to show that they are directly transformed into the prolegs of the larva (Lepidoptera) and the gonapophyses of the larva or imago (Orthoptera). Where they are not thus transformed directly, but first flatten out, we obviously have the primordia of imaginal discs, and the organs would belong to Deegener's sixth category. Reverting now to the absence of antennæ and thoracic appendages in apod larvæ and their presence in the preceding or embryonic and the succeeding or imaginal instars, we see that we have a case of precisely the same nature as that of the abdominal appendages, though clearer on account of the larger size of the cephalic and thoracic structures and their imaginal discs. But any such ontogenetic conclusion as Deegener draws from the abdominal appendages of the Noctuid larvæ would here land us in the absurdity of supposing that the imaginal antennæ and thoracic legs of such insects as bees, weevils and ants are not completely homologous with their embryonic antennæ and thoracic legs. We are bound to conclude that all insect embryos are polypod and that the most ancient known Pterygogenea, the Palæodictyoptera, as Handlirsch has shown, had well-developed abdominal appendages, which must have been ambulatory in the more remote ancestors. It is, therefore, simpler to suppose, even if embryology did

not furnish a great amount of evidence in support of this conclusion, that the ambulatory function has been revived in some of these appendages (*pedes spurii* of the caterpillars of Tenthredinidæ, Lepidoptera and Panorpatæ, *pedes scanesorii* of Dipteran and Coleopteran larvæ), while others have become portions of the ovipositor and sting of the female insects, than to suppose that these various organs have come into existence *de novo* through modification of abdominal sclerites. This view, which is now fashionable in Germany, has arisen through ignoring or misinterpreting the conditions in the insect embryo, attaching undue importance to supposed homologies of the sclerites of adult insects and supposing that the organization of the Pterygogenea is to be interpreted by means of the Thysanura. It is a pleasure to see that Deegener departs from the conventional view to the extent of regarding the so-called campodeiform larva in the Holometabola as a secondary and not as a primitive type. In this respect his views coincide with those of Lameere, Boas and Handlirsch.

All entomologists will probably agree with Deegener that the characters peculiar to the larva have "arisen during metembryonic life successively in adaptation to differences in the conditions of the environment." He discusses at some length the reasons for the larval retardation in the development of the wings, and in this connection gives an interesting account of the subimago of the Ephemeroidea, for the purpose of showing that an insect can actually undergo ecdysis after it has completely or almost completely developed its wings, but he does not emphasize the obvious fact that the wings of insects are organs primarily associated with the dissemination of the species, and, therefore, correlated ontogenetically with the maturation of the reproductive organs. The few larvæ that are paedogenetic (*Cecidomyia*) and the few beetles (*Pissodes*, Scolytidæ) that become imagines long before reproduction, though striking exceptions, can readily be explained as secondary adaptations. Attention is called to the reduction of the number of ecdyses and the manner in which pupation has become

associated with two of these in metabolic insects. The pupa of the Holometabola is regarded as being to a certain extent a phylogenetic stage, analogous to the subimago of the Ephemeroidea, but as having developed its peculiarities (quiescence, unchanged external form and profound internal changes) in correlation with the structural differences that separate the larva from the imago. These differences are described as follows:

In the Hemimetabola the whole development appears as at first progressively imaginipetal (total habitus), later as temporarily and progressively imaginifugal (provisional organs), with ontogenetic adaptations, and finally as regressively imaginipetal (involution of the provisional organs). In the Holometabola, on the contrary, development is at first regressively imaginifugal (total habitus and imaginal organs), then progressively imaginifugal (development of provisional organs of first and second order) and finally (in the pupa) progressively (total habitus and imaginal discs) and regressively imaginipetal (involution of provisional organs). Hence the Holometabola are characterized in the metembryonic portion of their life cycle by a regressively imaginifugal type of development, which changes to the progressively imaginipetal type in the pupa. In other words: Whereas the continuously progressive development of the Hemimetabola is not interrupted and is only slightly affected by the formation of provisional organs, the progressive development of the Holometabola up to the imaginal stage suffers a long interruption (during the larval stage) and is not resumed till the transition to the first imaginal stage (the pupa), in order to attain, by passing through this, the definitive imaginal form.

Deegener, like many other students of insect metamorphosis, regards the pupa as a teleological development which enables the organism greatly to lengthen its larval life, and through the magnitude and intensity of the changes which it undergoes, to drop out or fail to recapitulate, a great number of phylogenetic stages and thus to pass directly into the adult condition. The development of such a pupal stage, he believes, has been facilitated by the ability, so frequently observed in insects, to fast for long periods of time. In this connection he might also have called attention to the adaptation of the pupal stage

to tiding over unfavorable seasons (cold winters in temperate and boreal, dry seasons in tropical regions), as has been pointed out by Lubbock, Haacke, Handlirsch and others.

WILLIAM MORTON WHEELER

The Systematic Relationships of the Coccaceæ, with a Discussion of the Principles of Bacterial Classification. By CHARLES-EDWARD AMORY WINSLOW and ANNE ROGERS WINSLOW. New York, John Wiley & Sons. 1908.

The book before us is the completed results of work by these authors of which we have had preliminary information through articles in *SCIENCE*¹ and the *Journal of Infectious Diseases*.²

This work is by far the most important contribution to the purely scientific side of bacteriology which has appeared in a long time. It marks the beginning of a new era in bacteriological classification and nomenclature.

The systematic classification of the bacteria has always been extremely artificial and arbitrary. Outside of the three large morphological groups, the cocci, bacilli and spirilla, classification has probably never expressed natural relationships. However useful for purposes of identifying species artificial classification may be, it never reaches its highest function until it tells us more than whether a species has been previously described in the literature. It can never be really useful until it expresses for us the real position of the species in question in relation to other forms, and to some extent, at least, tells us the probable line of descent which the species has followed in its development from other forms. This is the ultimate goal which the classification of all living forms should seek.

A few attempts have been made to recognize certain "groups" among the bacteria, and undoubtedly some of these groups repre-

¹"A Revision of the Coccaceæ," *SCIENCE*, N. S., XXI., 1905, 669.

²"A Statistical Study of Generic Characters in the Coccaceæ," *Biological Studies by the Pupils of William Thompson Sedgwick*, Boston, 1906; also *Journal of Infectious Diseases*, III., 1906, 485.

sent natural families or genera. Some of these groups are based on morphological distinctions while others are simply held together by certain physiological resemblances. And in practically all cases as soon as the firm ground of morphological characters is left, and attempts are made to make use of physiological differences, we find systematic bacteriology becoming simply determinative bacteriology, and all semblance of natural relationships is lost in a confusion most bewildering.

It has remained for the work of the Winslows to bring order out of chaos, to show us how it is possible to delimit the different groups of bacteria and to determine their natural relationships, with just as sure a footing, whether we make use of morphological or physiological characters.

Their method of defining bacterial groups is by a study of the numerical frequency of various characters in a large series of cultures. It matters not whether the characters are morphological or physiological as long as they are measurable. It is true this method of defining species is not original with these authors; anthropologists and students of variation and heredity have developed it for the study of their particular facts. Even among bacteriologists it was being used at the same time that the work of the Winslows was going on by Andrewes and Horder in England for the classification of the streptococci. But it was our present authors who pointed out the importance of this method for work with the bacteria, and it is to them that all credit should be given for working out the method and applying it on a large scale to the problem of bacterial classification.

It is not necessary here to refer to the method of biometry. It depends on the fact that fluctuating variations, when measured in a considerable number of individuals, group themselves in a curve which follows the simple mathematical law of chance. If two large arrays of individuals are measured the curves obtained are practically identical. But if arrays from different origins are measured the shape of the curves will differ, as well as the position and height of the modes. Such

curves measure the peculiarities of a group as a whole, and serve to discriminate the different types, even though particular members of the groups are indistinguishable. By extending the observations to include the correlation of characters in the different racial types, the statistical method will indicate the systematic relationship of the different types.

As the authors themselves say:

The biometric methods, which have proved so useful in the study of the races of man, promise to be of even greater value in the systematic analysis of types among the bacteria, where so many factors combine to preserve varietal differences on so wide a scale. If individual strains only are considered, an infinite series of differences appear. If the same strains are considered statistically, that is, if the frequency of a given character be taken into account, it is apparent that certain combinations of characters are much more common than others. Measurement of almost any character by quantitative methods shows that the bacteria examined group themselves on a simple or complex curve of frequency. The modes of this curve indicate centers of variation about which the individuals fluctuate; and these centers of variation are the real systematic units of the group. The recognition of such centers, as specific types, offers the natural and satisfactory compromise between systematic multiplicity and vague generalization. The grouping of specific types is an even more important problem than the definition of the types themselves; and here the correlation data obtained by biometric study are of assistance. A true natural classification is tree-like and includes branches and twigs of varying grades of importance. Genera of bacteria should be aggregates of those specific types which are most nearly related; and the basis of the relationship will differ in each individual case. . . . Finally, the results may be analyzed with two ends in view. First, each center of numerical frequency, marking a group of organisms varying about a distinct type in regard to a single definite property, may be recognized as a species. Second, those species which are bound together by the possession of a number of similar properties may be constituted as genera, and larger groups of genera, still characterized by some characters in common, may receive the rank of families or sub-families.

The recognition of these principles will throw a flood of light upon all our future at-

tempts to classify the bacteria. It will give us a sound foundation upon which to build our systematic groups. It will give us a simple and natural nomenclature in place of the unwieldy generic names in use at present, and will do away with the tendency so noticeable now to use trinomial or even quadriminomial names.

Besides pointing out the proper way to work out the classification of the bacteria the authors have set us an example of just how to go about the work by their careful study of the Coccaceæ. They collected 500 different strains of cocci from different sources and submitted each one to a series of eleven definite, and in most cases, quantitative tests. The frequency curve for each character was plotted, the modes determined, and these modes were taken as the bases for the establishment of the various groups. The eleven characters were chosen after due deliberation and while there may be a difference of opinion as to the relative value of these characters and others which might have been selected, yet we must agree with the authors when they say that the eleven tests chosen furnished sufficient information to warrant the recognition of the most important natural groups. A further study of the correlation of these characters seems to point to the fact that these systematic units are marked by the general association of a number of independent characteristics. Such an association can be explained, our authors say, only on the ground of relationship, therefore the classification which they have arrived at is a natural one, and one which meets the requirements of expressing the natural relationships of the different groups.

The authors find eight genera among the Coccaceæ, each of which they define and discuss. To the bacteriologist familiar with the earlier classifications some very striking and totally unexpected results appear. First of these is the importance of pigment production as brought out by this method. Hitherto it has been taken for granted that such an easily modifiable character as the production of pigment was scarcely even of varietal rank. But a study of chromogenesis by the biomet-

rical method shows that the production of the various pigments is the property of certain well-defined types, and when we take into consideration the singularly perfect correlation between this property and the fermentation of the sugars, and with other characters, we must agree with the authors that it is really of genetic significance. Second, we find that the authors lay little stress on such characters as the shape and markings of colonies on gelatin or agar, the shape of the liquefaction in the gelatin stab, the luster or surface appearance of agar streaks, characters which we have been in the habit of considering important. They show that for the most part these characters are but the result of differences in general vigor of growth and in the rate of liquefaction of the gelatin. They summon sufficient evidence to support their position so that we are forced to agree with them. But they are careful to state that their conclusions apply only to the Coccaceæ and that some of these characters may be found important when other groups are studied.

The book closes with a summary of the genera and species of the Coccaceæ, an admirable key to these genera and species, and finally a complete bibliography and author and subject indexes.

While the work on the Coccaceæ is most admirably done and gives us a working basis for all future study of these forms, yet its real worth is not in its own intrinsic value, but in its immense suggestiveness for all future work in the classification of other groups of bacteria. We hope that this will be but the first of a long series of monographs dealing with other groups of the bacteria, all worked out along the lines which these authors have so well marked out for us.

F. P. GORHAM

BROWN UNIVERSITY

A Treatise on Gold and Silver. By WALTER R. CRANE, Ph.D. New York, John Wiley & Sons. 1908.

The preface states that "The object of this work with others of a series is to give a complete and accurate record of the development

of the mineral resources of the country and its influence on the various industrial activities throughout the United States," and that it "has been prepared with aid received from the Carnegie Institution of Washington, and is to form part of the Economic History of the United States, which is to be published by that Institution. . . . The work has been conducted under the supervision of Mr. Edward W. Parker" and its preparation "has occupied two years," etc., from January, 1906, to January, 1908.

Perhaps the value of such a contribution is enhanced by its character as a compilation, and this may give some excuse for the repetition of details under different heads. But the very semblance of statistical quality emphasizes the advantages which might have accrued from the presence of an adequate index or an expanded system of paragraphing. So very much of laboriously collected material has been itemized in the 720 pages, that thousands of entries would be necessary to properly catalogue them. This work has but 500 references in the index, and these are mostly equivalent to the titles of broad divisions of the text. There are typographical errors in proper names of the west, some displeasing errors in grammar and rhetoric and other literary blemishes, but these can all be corrected in later editions and are much less conspicuous than would be the case but for the heavy proportion of quotations, in which these defects do not appear.

There are seven chapters, covering various aspects of gold and silver. The first deals in a semi-philosophical way with precious metal mining as "a factor in the industrial growth of the United States," crediting this industry very largely with the development of civilizing influences, by the inception of agriculture, extension of transportation facilities, expansion of finance, stimulation of scientific enterprises, the upbuilding of mining schools and the general development of the mining industry.

The history of the discovery and growth of precious metal mining and metallurgy is then given in great detail, by geographic

divisions, followed by a full chronologic treatment, covering the period from 1518 to 1906.

This portion of the work bears evidence of painstaking library research, and probably the results are, all considered, as satisfactory as could have been anticipated by this method alone. It is cause for regret that an institution of the prestige of the Carnegie should not have availed itself of the services of reviewers in all parts of the country in order to preserve an even balance throughout the record. It is no disparagement to the able young author to suggest this; for he has performed uncommonly well an arduous task, in assorting his material and condensing it as he has done. The general impress is correct, remarkably so, indeed. Very few false conclusions are expressed, although some errors are apparent, which need not here be specified.

Chapter III. treats of "Occurrence and Association of Gold and Silver." It opens with a professedly cursory review of current theories of ore deposition, which is a model of perspicuity and a striking example of self-restraint in the presentation of the current aspect of a much-involved series of problems. The summary of it all is the quotation from A. G. Lock, which puts the case in a nutshell.

Following is a general discussion of the variety of mineral occurrences, ending with a review of prejudiced notions and their injurious effects upon the mining industry.

Then come 120 pages of detailed descriptions of occurrence, arranged alphabetically by states. This chapter gathers a vast array of facts, wholly unclassified and largely repetitive, but often useful in this form. There has been here no attempt to arrange this material more specifically, or to trace connection between the minor areas. Many more pages are taken up with the occurrence, geographically, of gold in gravels.

Only ten pages (chapter IV.) are given to the geologic distribution of gold and silver, and this deficit must be regarded as a blemish. It is true that the presentation in this concise manner bears abundant evidence of the author's thorough acquaintance with the subject

and of his ability to condense. But some might prefer the relegation of the prolix chapters which precede, to a separate volume, giving opportunity for more adequate treatment of subjects which appear to be slighted over much.

Chapter V. has 130 pages devoted to Mining Gold and Silver Ores and Gravels. This is well put together and presents a very fair outline of methods of mining, being very largely a series of quotations from leading authorities, although in some parts the author exhibits his own qualifications by presenting well-digested material in his own words.

In chapter VI. a similar arrangement of authoritative quotations, edited and connected by appropriate remarks, makes a generalized review of about 80 pages.

Nearly 100 pages (as chapter VII.) are given to statistics of production, compiled by geographic areas, as usual. This work has been well performed. Six appendices follow in the form of tables, recapitulating in detail the statistical matter previously given, under practically equivalent headings. These crowd a vast amount of particular information into little more than 60 pages, but they are by no means as complete as they might have been made by seeking the aid of many local co-laborers. As a convenient hand-book for ready reference by busy practitioners, the statistics and much of the technical matter quoted may be in useful form, and probably the whole will fill a want among the untutored who require pre-digested nutriment. The abundant references, though lacking the personal factor which would ordinarily attest their authority, add greatly to the value of the work.

The compiler has rendered good service faithfully and conscientiously, according to a plan apparently dictated by others. Perhaps it is premature to express any opinion upon certain features which might be otherwise rated if one really knew the purpose of the Carnegie Institution in having prepared the series of texts of which ostensibly this is the forerunner. For instance, under the head of *Extraction of Values*, no mention is made of

the flux smelting of gold and silver ores, concentrated in lead and copper menstrua. Although it is probable that this has been reserved for future volumes of the series, where the discussion may be more appropriate, there appears throughout the present volume a tendency to minimize the importance of the fact that the actual weight of silver annually extracted from placers and dry ores amounts to nearly four and one half times the weight of gold obtained from the same source. This is not an economic argument, to be sure, in favor of more generous treatment of the minor metal in a work purporting to deal with both. But the facts are that the weight of all silver extracted amounts to about fourteen times the weight of the gold, and that much more than three fourths of the total silver product (equal in value to one third of the gold product) is won by metallurgic processes designed primarily for the recovery of the silver. Moreover, the metallurgy of the baser ores, *per se*, is in many respects so distinctive that the collection of gold and silver therein is to be regarded properly as a separate industry. That is to say, the presence of the precious metals in ores limits and defines processes of treatment in such a manner as to make the grosser metals the real by-products.

Therefore, it would seem logical and profitable to discuss some methods to which little or no reference has been made in Dr. Crane's work.

Keeping always in mind the introductory words of this review, if it be fair to judge by them alone, the author appears to have compassed very well the task set by the Carnegie Institution. Probably no one else was better placed to perform this identical service by the means employed in executing it. One might prefer a different mode of treatment and the enlistment of others in the collaboration of data not readily accessible in print. But criticisms of this kind must not be permitted to obscure the patent fact that the writer appears to the very best advantage in those parts in which his subjects have given him more free scope for the exercise of his own abilities, and where dictates of modesty and

honor have not appeared to make rigid quotation essential.

THEO. B. COMSTOCK

LOS ANGELES, CAL.,

January 15, 1909.

Ueber das Wesen der Mathematik. Rede gehalten am 11 März, 1908, in der öffentlichen Sitzung der k. Bayerischen Akademie der Wissenschaften. Von Dr. A. Voss, Professor der Mathematik in München. Pp. 98. Leipzig und Berlin, B. G. Teubner. 1908.

The numerous and valuable earlier publications of the author of the present address inspire confidence in his ability to treat such a general subject in a scholarly and helpful manner. The reader will find that this confidence has not been misplaced, for the address is not only replete with important suggestions in regard to fundamental questions in mathematics, but it also emphasizes those elements which point towards rapid progress in the near future and thus awaken a healthy optimism. It seems especially suited to widen the outlook and to arouse energizing enthusiasm on the part of the young mathematician who may fail to appreciate the dignity and the beauty of abstract thought.

The author begins his address by the statement that we are living in the epoch of natural sciences and technology, and he quotes approvingly the remarks of Galileo:

True philosophy explains nature, but no one can understand her except those who have learnt the language and the symbols by means of which she speaks. This language is mathematics and the symbols are mathematical figures.

The bearing of mathematics just mentioned tends to explain why this subject is constantly taking deeper root in the educational systems of the world, notwithstanding the fact that it is "the most unpopular of all the sciences; it is a part of the essence of a true science to be unpopular."

The brief introductory remarks are followed by a rapid sketch of some fundamental facts in the history of mathematics. Beginning with the Egyptian work, written by Ahmes nearly four thousand years ago, which claims to give "Directions to obtain a knowledge of

all dark things, all secrets contained in the things," our author considers the historical development of a number of fundamental mathematical concepts and symbols. He generally follows the "Prince of mathematical historians," Moritz Cantor. In one instance, however, he adopts a view which is not in accord with the most recent work of Cantor, viz., as regards the question of the origin of zero and the positional arithmetic. Ten years ago it was generally believed that these discoveries were due to the Hindus, while the most recent work of Cantor makes a Babylonian origin appear much more plausible.

As may be inferred from the heading of the address, emphasis is placed upon those mathematical concepts which border on the domain of philosophy. Among the questions which receive considerable attention are the following: definitions of mathematics, relations between mathematic and logic, the development of the concept of number, higher complex number systems and different points of view as regards ordinary complex numbers, different theories in regard to ordinary fractions and irrational numbers, continuity and limit, importance of the concept of function, and suggestions as to changes in the subject-matter to be used for instruction in secondary schools. The address is written in a popular style and should interest the man of general culture as well as the professional mathematician.

UNIVERSITY OF ILLINOIS

SCIENTIFIC JOURNALS AND ARTICLES

The Journal of Experimental Zoology, Vol. VI., No. 1 (January, 1909), contains the following papers: "A Study of Growth in the Salamander, *Diemictylus viridescens*," by Ada Springer. "Studies on Chromosomes—IV., The Accessory Chromosome in *Syromastes* and *Pyrrochoris*, with a Comparative Review of the Types of Sexual Differences of the Chromosomes," by Edmund B. Wilson. This paper is devoted to a reexamination of two forms heretofore studied by Gross. It shows that sex-production in these forms agrees in principle with that seen in other insects. In *Pyrrochoris* the spermatogonial number is 28

and a typical odd chromosome is present. In *Syromastes* the spermatogonial number is 22, the "accessory" being represented by two chromosomes, and the number 24 is inferred for the female. A general review is given of the facts thus far determined in this field. N. M. Stevens contributes "Further Studies on the Chromosomes of the Coleoptera" and "An Unpaired Heterochromosome in the Aphids." David Day Whitney writes on "The Effect of a Centrifugal Force upon the Development and Sex of Parthenogenetic Eggs of *Hydatina senta*." The unsegmented eggs were centrifuged so that their contents were separated into three layers. These layers were variously arranged in their relation to the first cleavage plane and consequently a different distribution of the egg material occurred in each of the cells at the first cleavage. From such eggs normal individuals developed, grew to maturity, and produced normal offspring. No change in the sex ratio occurred. The same author has an article on "Observations on the Maturation Stages of the Parthenogenetic and Sexual Eggs of *Hydatina senta*." In the female parthenogenetic egg there is no reduction in the number of chromosomes during maturation but in the male parthenogenetic egg and also in the fertilized egg there is a reduction in the number of chromosomes. One polar body is formed by the female parthenogenetic egg and two polar bodies are formed by the male parthenogenetic egg.

A NEW VARIETY OF ASYMMETRY EXHIBITED BY THE NITROGEN ATOM

A NUMBER of organic compounds are known the isomerism of which is due to the different spatial arrangement of certain groups around a nitrogen atom. The most familiar examples are the oxines, such as benzaldoxine, which exists in the forms,

termed the *syn*- and *anti*- modifications, respectively.

A second variety of isomerism is recognized which is dependent on the fact that the nitro-

gen atom is linked to five dissimilar groups, as, for example, in the compound,

which exists in three forms. One is optically inactive (racemic) and the other two rotate the plane of polarized light to the right and left, respectively.

Similar varieties of isomerism are, of course, common in the case of analogous carbon compounds free from nitrogen.

Hitherto it has been believed that the difference in optical behavior mentioned above could not be exhibited unless all five of the groups linked to the nitrogen were unlike, but J. Meisenheimer¹ has just shown that this is not the case.

When methylethylaniline,

is treated with hydrogen peroxide, in presence of sulphuric acid, methylethylaniline oxide,

is formed. It is a crystalline, basic substance and is optically inactive. By the fractional crystallization of its *d*-bromcamphorsulphonic salt it is separated into two modifications. From these the corresponding free bases may be isolated and other salts prepared. These free bases are relatively stable and they rotate the polarized light to the right and left, respectively, the rotation being equal in degree.

It is, at present, uncertain whether these optically active free bases have the anhydro formula given above, with the double linkage between nitrogen and oxygen, or whether they are dihydroxides,

In either case, however, the isomerism is of an entirely new type. It will be interesting to see whether it is possible to prepare analo-

¹ *Ber. deut. Chem. Ges.*, 41, 3966, 1908.

gous compounds of the carbon series, free from nitrogen.

RUSSIAN RESEARCH IN METABOLISM

THE activity of Russian investigators in problems of animal nutrition and metabolism in general has been but imperfectly noted by the large majority of workers in metabolism. This is in large part due to the fact that in spite of increasing interest in international cooperation in scientific research in all branches, the Russian language remains, and probably will continue to remain, a distinctly unintelligible vehicle for conveying scientific communications to the world at large. More recently at least one Russian journal is issuing simultaneously an edition in French.

Recognizing the great importance of many of the earlier Russian researches, the Office of Experiment Stations of the U. S. Department of Agriculture has from time to time had translated and published abstracts of much of the Russian research in that particular branch of science dealing with metabolism. These abstracts were translated in large part by Professor Peter Fireman, formerly of the George Washington University, and the admirable digest of metabolism experiments by Atwater and Langworthy¹ contains many of them.

A dissertation entitled "Production of Heat by Healthy Man in the Condition of Comparative Rest," by A. Likhachev, is especially valuable as giving a complete description and tests of the Pashutin respiration calorimeter. This was translated at the instance of the Office of Experiment Stations, U. S. Department of Agriculture, by Dr. Fireman. Copies of the translation are on file at the Nutrition Laboratory and also at the Office of Experiment Stations, U. S. Department of Agriculture.

In connection with the preparation for pub-

¹ Bulletin 45, Office of Experiment Stations, U. S. Department of Agriculture, 1898.

lication of the results of a series of experiments on fasting men made at Wesleyan University, I arranged with a young Russian school teacher, H. Levin, to translate completely a lengthy article entitled "Metabolism during Fasting," by A. Sadovyyen. This article is of interest in that it describes a series of experiments on a fasting man in the Pashutin respiration chamber. The translation is preserved in the reading room of this laboratory.

On a recent visit to a number of European laboratories it was my good fortune to include several of the laboratories in St. Petersburg, and there I came into intimate contact with a great deal of research which was to me wholly unknown. I found that in certain instances the briefest kind of an abstract had been noted in some of the German abstract journals, but nothing approximating an adequate digest of this work had appeared as yet in anything but Russian. Thanks to the kindness of Professors Likhachev and Avroroff and Dr. Kartaschefsky, many important monographs were placed in my hands and, on my return to America, arrangements were made for their translation.

Professor Likhachev sent to the Nutrition Laboratory a copy of Pashutin's treatise on experimental pathology. This large work, consisting of two bulky volumes, contains a great deal of new, unpublished material, particularly in the section (some 800 pages) dealing with inanition. During the past year the whole section on inanition has been completely translated by Michel Groosenberg. This valuable work contains a large amount of original material, chiefly from Albitsky's laboratory, and is of importance to all workers in animal or human nutrition. The translation has been typewritten, manifolded and bound and copies of this translation are deposited in the surgeon general's library in Washington, the New York Public Library, and in the John Crerar Library in Chicago. Two other monographs presenting the results of experiments on man in the Pashutin respiration calorimeter are "The Influence of Alcohol on the Heat and Gas Exchange in

Man" and "Investigations of Gas and Heat Exchange in Fevers," both by A. Likhachev and P. Avroroff. Finally, two articles by Dr. Kartaschefsky reporting experiments with the small Pashutin respiration apparatus have been translated. They are entitled "The Influence of a Lack of Oxygen on the Exchange of Matter and the Heat Production in Animals" and "On the Influence of the Surrounding Temperature upon Animals in a Gas-Atmosphere poor in Oxygen."

These articles were translated in part by Mr. Alexander Rose, of Boston, Mr. Michel Groosenberg and Miss Anna Monossowitch, who is at present engaged in Russian translation at the Nutrition Laboratory.

Thus it is hoped to keep American workers in nutrition in more intimate contact with the admirable Russian researches that have as yet been practically inaccessible. Arrangements have been made with Professor Likhachev whereby all articles dealing with problems of metabolism can be sent to this laboratory for translation. From time to time the titles and short abstracts of these articles will be published in some scientific journal.

SPECIAL ARTICLES

A MENDELIAN VIEW OF SEX-HEREDITY

Two important contributions have recently been made to the discussion of sex-inheritance. In each a somewhat different view is presented, yet the two, I believe, are not irreconcilable, and if coordinated, will give us a truer conception of the whole matter than we have had before. I refer, on the one hand, to the recent vice-presidential address of Professor Wilson,¹ and, on the other, to the combined work of Bateson, Punnett, Doncaster, Durham and Marryat, published in Report IV. to the Evolution Committee of the Royal Society.

In 1908² I advocated the view that sex is in-

herited as a Mendelian character. The idea was not original with me. The suggestion came from the now famous Report I. of Bateson and Saunders. The fact has since come to light through Mendel's posthumously published letters³ that Mendel himself had been impressed by the parallelism between the phenomena of sex-inheritance and those of ordinary Mendelian inheritance. Indeed, the parallelism is so complete and striking that we can scarcely question the existence of a like basis for the two sets of phenomena.

Professor Wilson, to be sure, argues against what he terms "Mendelian theories" of sex-heredity and advances a somewhat different theory of his own. In reality, however, his theory, while an improvement upon its predecessors, is no less Mendelian than they, but rather more so, as I shall attempt to show.

Great advance has been made since 1903 in our knowledge of Mendelian inheritance in general, as well as of sex-inheritance, and it is noteworthy that in restating our knowledge in the two fields similar changes must be made in both. For example, we formerly said regarding crosses between rodents of different colors that "gray is dominant over black" and that "black is dominant over yellow," meaning that the contrasted characteristics were antagonistic and one excluded the other in crosses. As we now look at the matter, gray is not antagonistic to black, but contains an additional element which is wanting in black. The correctness of this view is shown by the fact that black can be changed to gray by a cross which introduces that additional element. A similar relation holds between black and yellow; black is yellow plus something else, and this something else may actually be added to yellow (by a cross with brown, for example) converting it into black.

Similarly as regards sex, in 1903 I expressed the view that male and female are antagonistic members of a Mendelian pair, one excluding the other. Such a view is inadmissible in the light of our present knowledge. What we should say is that the female is the male condition plus something else. Male-

¹ SCIENCE, January 8, 1909.

² Bulletin, Mus. Com. Zool., Vol. 40, p. 189.

³ Abh. math.-phys. Klasse d. k. Sachs. Gesellsch. d. Wiss., Bd. 29, p. 185, Leipzig, 1905.

ness is not, then, the Mendelian allelomorph to femaleness, but a differential factor between male and female is allelomorphic to absence of that factor. Presence of that factor means femaleness, absence of it means maleness. This differential factor is inherited as a Mendelian character dominant over its absence.

Such a statement will, I believe, bring into harmony the seemingly discordant results of Wilson, of Correns, and of Bateson and his associates. For Correns urges the view, as I did in 1903, that the male and female sex-characters as such are inherited. He believes further that the female organism is a homozygous recessive (♀♀) and the male a heterozygous dominant (♂?), for he finds that the egg-cells of *Bryonia dioica* all transmit a female sex-tendency, whereas the pollen cells transmit, half of them the female tendency, half the male tendency. His facts are unquestionable. I question only the supposed recessive nature of the female sex-character.

Wilson cautions us against the view that sex as such is inherited, believing that the difference between the two sexes is in reality a quantitative one. He finds the female characterized by the possession of two X-chromosomes, the male by one, and regards a second x-chromosome as the differential factor between male and female. In the view that the essential difference between the sexes is a quantitative one, Wilson makes general an assumption made earlier by Morgan⁴ for a particular case.

This suggestion seems to me very helpful. Among other things, it clears up fully the long mysterious matter of sex-determination in the honey bee, of which I gave in 1903 an interpretation since proved to be wrong. But though we regard the distinction between male and female as quantitative, we must not forget that it is discontinuous. *The female is the male condition plus a distinct unit-character Mendelian in heredity.*

We must also not follow Professor Wilson too closely in his assumption "that a single

X-element in itself causes or determines the male tendency, while two such elements in association create, or at least set free, the female tendency." For we shall presently see reasons for believing that in certain cases *one* X-element may determine the female tendency, while *no* X-element may determine the male tendency. But in both categories of cases alike the essential difference between male and female would seem to be one X-element, which the female possesses over and above the male.

We may leave open the question whether or not the "X-element" of Wilson is the actual material basis of this differential Mendelian unit-character of sex. The X-element at least behaves in cell-division as we must suppose that the basis of a Mendelian character would behave, and it will be convenient in what follows to treat it as actually representing such a basis.

Wilson's hypothesis will account satisfactorily for the experimental results of Correns, for it necessitates the production in gametogenesis of eggs all alike in sexual tendency, bearing X, but it calls for the production of spermatozoa of two different sorts, half of them bearing X, half of them without X. Eggs fertilized by the former should produce females (XX), those fertilized by the latter should produce males (X). Correns's observations accord with this interpretation.

But the Wilson hypothesis breaks down if we attempt to extend it to the cases discovered by Bateson and his associates. For in these it is evident that the eggs, not the spermatozoa, are dimorphic in sex tendency, whereas the spermatozoa are all alike. We can not reconcile such a condition with the hypothesis that XX produces a female, X a male. But the condition in question does harmonize with the assumption, $X = \text{a female}$, $\text{no-X} = \text{a male}$, and this condition, no less than that described by Correns for *Bryonia*, agrees with the more general assumption that the female possesses one more X-element than the male.

The cases to which reference has been made in which the female produces eggs with different sex-tendencies, but spermatozoa all with

⁴ SCIENCE, Vol. 21, 1905; *Am. Naturalist*, Vol. 41, p. 715, November, 1907.

the same sex-tendency, are, first, the moth, *Abraax grossulariata*, and, secondly, the canary-bird. The two cases appear to be similar, but as the former has been more fully worked out, we may confine our attention to that. The case of *Abraax* has already been presented in part to the readers of SCIENCE by Bateson and Punnett.*

This moth has a rare variety, *lacticolor*, known originally only in the female sex. For brevity in description we may call the typical *grossulariata* condition G, and the *lacticolor* condition L. The latter is a Mendelian recessive to the former.

Cross 1.—The cross $L♀ \times G♂$ gives only G offspring in both sexes, but of course all bearing L as a recessive character. See Table I.

Cross 2.—Heterozygotes (produced by cross 1), when bred inter se, produce $G♀$, $G♂$ and $L♀$, but in no case $L♂$ offspring.

Cross 3.—A heterozygote $G♂$, mated with $L♀$, produces all four possible combinations, $G♀$, $G♂$, $L♀$ and $L♂$. "The $L♂$ s thus produced were the first that had ever been seen." Now comes the most remarkable part of the whole story.

Cross 4.—When the newly produced $L♂$ s were mated either with heterozygous $G♀$ s produced by cross 1, or with wild $G♀$ s, the offspring were all G in the male sex, all L in the female sex.

Cross 1 establishes beyond question the recessive nature of the color character L. Cross 4 shows that the $G♀$, whether cross-bred or wild in origin, is heterozygous in color-character, bearing L as a recessive character. No homozygous $G♀$ s have been found. Crosses 1 and 3 show that the male may be, as regards character G, either homozygous, GG, or heterozygous, GL, and cross 3 shows that it may also be homozygous in L, that is, LL. In other words, there is no correlation between the male sex-character and either color-character. There does, however, clearly exist repulsion between the female sex-character and the color-character G, so that, whenever an alternative is offered, femaleness and L go into one gamete, maleness and G into another.

But such alternatives manifestly occur only in oogenesis, not in spermatogenesis. In no other way can we account satisfactorily for either the difference in result between the reciprocal crosses, 1 and 4, or the failure of cross 2 to produce the group $L♂$.

Bateson completes the explanation by offering the further suggestion that there is no disjunction of the sex-characters in spermatogenesis because the male does not carry the female sex-determiner at all, but is homozygous, $♂♂$. Consequently, when the L character once gets into a male individual, as by cross 1, where heterozygous GL♂s are produced, then in the spermatogenesis of such an individual gametes are sure to be formed in which the male character is associated indifferently either with G or with L. This, however, permits of the production of (homozygous) $L♂$ s only in cases where the egg bears the $♂$ character associated with L, a condition realized in cross 3, but not in cross 2 or cross 4. Doncaster summarizes the case in a table, which is here reproduced as Table I.

TABLE I

Abraax crosses, Doncaster's interpretation

	Parents	Constitution	Gametes	Offspring
Cross 1	Lact. female Gross. male	$LL♀♂$ $GG♂♂$	$L♀, L♂$ $G♂, G♂$	$\{ GL♀♂ = \text{gross. female}$ $GL♂♂ = \text{gross. male}$
Cross 2	Heterozygous female Heterozygous male	$GL♀♂$ $GL♂♂$	$L♀, G♂$ $G♂, L♂$	$\{ GL♀♂ = \text{gross. female}$ $LL♀♂ = \text{lact. female}$ $GL♂♂ = \text{gross. male}$ $GG♂♂ = \text{gross. male}$
Cross 3	Lact. female Heterozygous male	$LL♀♂$ $GL♂♂$	$L♀, L♂$ $G♂, L♂$	$\{ GL♀♂ = \text{gross. female}$ $LL♀♂ = \text{lact. female}$ $GL♂♂ = \text{gross. male}$ $LL♂♂ = \text{lact. male}$
Cross 4	Heterozygous female Lact. male	$GL♀♂$ $LL♂♂$	$L♀, G♂$ $L♂, L♂$	$\{ LL♀♂ = \text{lact. female}$ $GL♂♂ = \text{gross. male}$

If, in Table I, we substitute X for the symbol ♀, discarding the symbol ♂ altogether, and consider all individuals bearing X to be

* Vol. 27, p. 785, May 15, 1908.

females, we get no change in the character of the results shown in the column headed "offspring." See Table II. That is, the facts

TABLE II
Abrams crosses, an alternative interpretation

	Parents	Constitution	Gametes	Offspring
Cross 1	{ Lact. female Gross. male	LLX GG	LX, L G, G	{ GLX=gross. female GL=gross. male
Cross 2	{ Heterozygous female Heterozygous male	GLX GL	LX, G G, L	{ GLX=gross. female LLX=lact. female GL=gross. male GG=gross. male
Cross 3	{ Lact. female Heterozygous male	LLX GL	LX, L G, L	{ GLX=gross. female LLX=lact. female GL=gross. male LL=lact. male
Cross 4	{ Heterozygous female Lact. male	GLX LL	LX, G L, L	{ LLX=lact. female GL=gross. male

agree with the hypothesis, $X = \text{♀}$, $\text{no-}X = \text{♂}$, quite as well as with the Bateson-Doncaster hypothesis. But if we apply Wilson's $XX = \text{♀}$, $X = \text{♂}$, hypothesis to the case, the expectations for crosses 3 and 4 will be exactly interchanged; cross 3 should produce only $L\text{♀}$ s and $G\text{♂}$ s, whereas cross 4 should produce all four possible combinations. This fact is decisive against the Wilson hypothesis and for that of Doncaster, or for such a modification of it as I have attempted to present.

We may, it seems to me, summarize our present knowledge of sex-inheritance under one consistent scheme, somewhat as follows:

1. Sex is not directly controlled by the environment, but is determined by internal (gametic) factors.

2. The determination of sex depends upon the presence in the zygote of a factor or factors which are inherited in accordance with Mendel's law.

3. Femaleness, that is, the capacity to produce macrogametes (eggs) depends upon the presence of some factor wanting in the male.

4. The presence of this factor is in heredity dominant over its absence.

5. As regards the transmission of this factor we can recognize two distinct categories of cases:

A. Femaleness is attained only when the differential factor is doubly represented in the individual. In such cases the female is a homozygote (XX), and the egg invariably transmits the differential factor. Sex determination then rests with the male parent, for half the spermatozoa possess the differential factor and half lack it. The female is a homozygous dominant, not, as Correns supposed, recessive; whereas the male is a heterozygous dominant, pure recessives being unknown.

B. Femaleness is attained whenever the differential factor is present in one only of the conjugating gametes which produce the individual. The gamete which transmits the differential factor is of course the macrogamete (egg), since this factor is not possessed by the male parent. The female is a heterozygous dominant, the male a pure recessive; homozygous dominants are unknown.

The experimental proof for the existence of these two categories of cases has been produced for class A by Correns, and for class B by Doncaster and others. Cytological evidence which strongly supports the interpretation given to class A has been produced by McClung, Stevens, Morgan and especially by Wilson. This evidence is fully corroborated by the work of many others. Direct cytological evidence for the existence of class B is not known at present, but may confidently be looked for.

6. The hypothesis which I advanced in 1903, that both sexes are in the same species sex-heterozygotes, is not supported by the considerable body of evidence since accumulated.

If, as seems probable, the differential sex-character has its cytological basis in the "X-element," as Wilson designates it, it becomes an interesting question, what is the cytological basis of those numerous morphological characters possessed by the male, but wanting in the female. For it is a well-known fact that such secondary sexual characters are in general both more numerous and more striking in the male than in the female. For this reason the male has been called the "progressive" sex, which takes on new or striking characters, that may or may not later be

shared with the female. Can we reconcile these facts with the idea that the female is a male plus something else? I think so, but we must concede also the possibility that the male may possess certain qualities not merely not manifested by the female, but even not possessed by it. I would offer the suggestion that we have a mechanism suitable for the transmission of characters exclusively male in the Y-element described by Wilson, the "synaptic mate" of the X-element, which takes the place in the gamete of a lacking X-element, and which would not be borne by a gamete possessing that element. If the primary difference between male and female is a defect in the male, the lack of something present in the female, that very defect would constitute a likely place in the germ-cell for new structures to find lodgement, which, behaving as the "synaptic mate," the material counterpart of the X-element would pass only into gametes lacking X, and so would produce structures peculiar to the male, and unrepresented in the female.

If this idea should prove to be correct, then we should have to revise the generalization to which Wilson gives expression "that so far as the eggs are concerned (and also those spermatozoa that contain the X-element) . . . every gamete contains factors capable of producing both the male and female characters, and that this is also true of all the zygotes." If the Y-element should prove to be the basis of characters purely male, then such characters would not be represented at all in gametes containing X, and cases like that described by Darwin, in which the hen-pheasant transmits to its hybrid male offspring in crosses characters of the male of its own species, could have but one interpretation, viz., that the hen-pheasant produces gametes lacking the X-element, as well as those which possess it. In other words, the hen-pheasant would seem to be a sex-heterozygote and so to fall in the same category of cases as the moth, *Abraxas grossulariata*, category B already mentioned. If so, the male pheasant should be incapable of transmitting in crosses characters peculiar to the female pheasant, if such exist.

This line of thought emphasizes the impor-

ance of reciprocal crosses in unraveling the mysteries of sex-inheritance and of the inheritance of secondary sexual characters. If the two categories of cases A and B really exist, there should be this difference between them. In A the male may transmit recessive characters peculiar to the female, but the reverse relation does not hold. In B, the female may transmit recessive characters peculiar to the male, but the reverse relation does not hold.

Further, there should be a difference in the two categories of cases in the Mendelian nature of fixed sexually dimorphic conditions. In category A, male secondary characters must be dominant in order to be fixable, i. e., they must be represented in the Y-element by something not found in the X-element, but which will manifest itself even in the presence of the X-element. In category B, male secondary characters must be recessive in order to be fixable, i. e., they must have their basis in the absence from Y of some element present in X, which absence will not be manifested if even a single X-element is present. For example, in *Abraxas* the pale *lugens* character is manifestly a defect character, due to lack of something found in *grossulariata* individuals, L being recessive to G. The gametic coupling of the female character with the *lugens* character, whenever a doubly differential cell division occurs, is doubtless due to the fact that the *grossulariata* character acts as the "synaptic mate" to the X-element, leaving absence of G (i. e., L) associated with X. If in this cell-division G were associated with X, instead of with Y, then it would be possible to produce a stable sexually dimorphic race, with L♂s and G♀s, but the relation being what it is, no stable race can be formed in which the two sexes are G and L, respectively, but only races purely G or purely L in both sexes.

On the hypothesis suggested in this paper, accordingly, we can account for the fact that secondary sexual characters are more common in the male, if not its exclusive possession, even though the male is, as compared with the female, a defect race, or regressive variation. Transference to the female of characters originally possessed by the male alone could be accounted for by the duplication of the Y-element

in a heterozygous (XY) germ cell. In this case Y would become the "synaptic mate" of Y, and X would be left once more (as originally) without synaptic mate, fit instrument for the origin of new progressive variations, the characters determined by Y now being the common property of both sexes.

A clue to phylogenetic histories would thus be afforded us, giving point to such variations as the *lugens* variety of *Abraxas*. Thus it is possible (though nothing but pure speculation in the light of our present knowledge) that *lugens* may be the phylogenetically older form, characteristic originally of both sexes, and that the *grossulariata* character may have had its beginning in gametes lacking the X-element, i. e., in a Y-element formed as the "synaptic mate" of X. Thus would arise *grossulariata* males, but the new character being dominant over its antecedent (*lugens*) would quickly be transferred to the females, since these contain a no-X (i. e., a Y) element, in common with the males. But the X-element, as shown by Doncaster's experiments, is still unassociated in a gamete with the new *grossulariata* character, and so the fixing of that character upon the species is not yet complete.

How now may the occasional reappearance of *lugens* females be accounted for? Simply by reduction divisions, in spermatogenesis, in which the two Y-elements fail to segregate as normally, forming in consequence a sperm-cell which lacks Y (the *grossulariata* character). If such a sperm-cell fertilizes an egg of the constitution LX, a *lugens* female is certain to result.

If, as has been suggested, the presence in one gamete and absence from another produced by the same cell-division, of an "odd chromosome" (or other X-element, whether chromosome or something else) is itself a circumstance which favors the origin of new characters in the defective (male-forming) gamete, then we shall perhaps come to attach less importance than has sometimes been done to the supposed influence of sexual selection in evolution. For sexual selection, as has often been pointed out, can in no case account for the origin of new characters, and it is

extremely doubtful whether it plays any part even in their preservation.

Striking new characters produced by internal causes doubtless persist unless suppressed by external causes, i. e., unless they disqualify their possessor for competition in the struggle for existence. There is no more reason for supposing that males gain their gay colors and markings from choice on the part of the females, than that females owe their modest colors to choice on the part of the males. But if, as suggested, the very mechanism of gametogenesis is adapted for the production of new characters in the male, then we are afforded a basis for their explanation, without invoking external causes. Recent investigations tend strongly to show that variations of evolutionary significance are primarily internal. This is unmistakably so in the matter of sex. Even in cases where sex is subject to control by environmental factors, as in aphids and daphnids, the environment acts indirectly apparently through the control of the same internal factors which govern sex in other animals. If the mechanism which I have suggested is not their true source, then we may well look for other possible internal mechanisms.

Orthogenesis also, the persistent tendency of an organism to vary in a particular direction, irrespective of the action of natural selection (if indeed orthogenesis be a reality, which, however, I do not assert), orthogenesis then would find an explanation along similar lines to those which I have suggested. For if a Y-element arose because of the very lack of X, then it would be natural for it to continue to grow until it became the full complement of X.

I make no apology for offering the hypothesis, or hypotheses, contained in this paper. I would have every reader recognize as fully as I do that they are hypotheses, and I shall be quite content if they suggest lines of investigation which will further elucidate the nature of sex and the manner of its inheritance.

THE AMERICAN COLLEGE AND LIFE¹

It is in no wise due to my own choice and moving that I am called upon to take part in this discussion. Just because philosophy calls for so much reflection, I consider it a proper part of a philosophical student's business to keep himself relatively naïve, unreflective and directly practical regarding at least some important portion of his own life's business. Upon certain problems it is my duty to reflect, in as critical a fashion as I may. I do reflect about those problems with a good deal of persistence, and I discourse upon those topics at wearisome length. They are topics of logic, of metaphysics and of general ethical doctrine. In the rest of my life I try to stick to business without much reflection. Such naïveté need not mean, I hope, either carelessness or unfaithfulness. It may mean, and in my case I hope that it does mean, so far as that part of my vocation is concerned, practical absorption in tasks. Now part of my vocation is that of a teacher. And while, as I said, I reflect a great deal upon the metaphysical and other topics concerning which I have to teach, I have never been disposed to reflect much about the practical business of teaching itself. I teach as I can. When I observe that I teach ill, I try to mend my ways. I can not tell much about how I try to mend them. I can not formulate a theory of teaching. When I observe that a student

MSS. intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

¹ An address given before the Section of Education at the Baltimore meeting of the American Association for the Advancement of Science.

is inattentive, I try to interest him. When he is wilful, I try to get past his wilfulness as I can. I do not know what, as a teacher, I accomplish. I simply try my best. And I suppose that, for me, with my limitations, such relatively unreflective efforts to do my best are most useful to me as a teacher. And similarly, as to the general conduct of a college, I avoid theories. I attend various faculty meetings, and have a natural and somewhat uncritical fondness for the wisdom of my administrative leaders and colleagues. But I do not understand college administration, especially under modern conditions. I have listened pretty patiently to some long and learned faculty debates upon the problem of college entrance examinations. I have never been able to comprehend the subject. I prefer to reflect upon such straightforward and solid problems as that of the absolute. I leave such airy topics as the reform of the secondary schools to those who know about them. There seem to be many such knowing persons. I hope that together they have wisdom enough to meet the issues of their time. But never, by my own choice, would I venture to take part in the counsels of the wise regarding the theory and the general conduct of what is called the American college. For I know that I am merely a servant of the college, who can do best by holding fast to my own work. Since, however, men much wiser upon this topic than I am have insisted upon my taking part in this debate, I offer my views simply as the personal impressions of a college teacher, who has tried for years to be faithful to his calling, but who has no general theories as to the college. I come here simply as *ein Thor*, who, if I have any sort of insight into my practical tasks as a teacher, or into the value of the American college for life, possess this insight merely as one who am

perhaps a very little *durch Liebe erleuchtet*. I am told that testimony is desired here, as well as comprehension. Upon these topics my comprehension is of the slightest. Let me merely offer my testimony.

I may begin the summary of my impressions by relieving you of the notion that I have any right to speak as a representative of a distinctively Harvard point of view. I have tried to serve Harvard as I could for more than a quarter of a century. And my personal love for Harvard and for my work there is indeed at the heart of whatever I can say. But I am a graduate of the University of California. My educational prejudices were first formed under the conditions of far western state university life, and were later modified by study at the Johns Hopkins University. I keep many of my early prejudices still. And they result in this impression, viz., that some of the most important problems of what your title calls the American college will have to be worked out under the conditions of the great state universities. The center of gravity of our future American academic life can not always, can not, I think, very long remain east of the Alleghenies. Through a perfectly natural and inevitable evolution, the state universities of the middle west and of the far west, supported as they are, and will be, by the vast resources of their own communities, and guided by constantly improving educational ideals, will within a generation or two occupy a very nearly central place in the academic life of our country. I do not imagine that the older eastern institutions will fail also to advance rapidly and effectively. But they will in many ways need to undertake functions more closely analogous than their present functions are to those of the state universities. That is, as institutions whose influence

will more and more be felt in the organization of the whole system of public education in their respective provinces, as trainers of our new coming foreign population to the duties of citizenship, as servants of the state, as centers of guidance, both for technical education and for research, the older eastern universities will, like the western state universities, undertake a variety of tasks which they now very unequally recognize and pursue. Hence, as I believe, when we think of the future of the "American college," we should remember that this future is bound up, inseparably, with the future of the American state universities, and with the future of institutions whose functions will be in more and more ways analogous to that of the state universities. It is, therefore, simply useless to try to think of something called "the college" as if its function could be sharply separated from that of very various grades and types, both of technical and of professional schools. I think that the usual disposition of many educational theorists to insist that, for the sake of a dictionary definition of the term college, and for the sake of some historical tradition, such a sharp separation of the functions of "the college" from the technical school on the one hand, and from those of the graduate professional school on the other hand, should be made where it does not at present maintain itself—I think, I say, that this usual disposition is misleading. Look at the state universities and see what the work of "the college" with them always has been. It is a work that in various parts of the same institution may involve training in agriculture, in mining, in classics, in political science, in philosophy, in music and in civil engineering. One may protest as one will that one misuses the term college when one talks of a college of agriculture, and that one ought instead to speak of a tech-

nical school of training in agriculture. One may raise as much as one pleases the question whether a liberal education, devised by some one who does not love agriculture, should first be required of students of agriculture, who should then only be allowed, as graduates, to undertake their more technical studies. One may insist as one chooses that agricultural schools, if they are to exist at all, should be separated from the institutions that undertake to educate their pupils in the sense of a higher cultivation. But whatever one thus does by way of formulation, of definition, and of criticism, the state universities will continue to show that the best thing you can do for an agricultural school is to make it an integral part of an academic institution wherein Greek and metaphysics and history and the science of government are also taught; while one of the best things that you can do for the young men who are to be trained in the humanities is to keep both them and their teachers in pretty close contact with the pupils and teachers who are engaged in technical studies. The history of more than one western state university has been the history of the gradual humanizing of a little group of technical schools. A college of agriculture, as it grows, adds to its resources, perhaps, a department of music, a "classical college" is joined to schools of engineering which have already been formed, and thus something is developed which is indeed a highly composite institution. Its functions include those of graduate and undergraduate, technical and professional schools, and also the functions of which we are talking when we speak of the American college. The interesting feature of such institutions is that our lines of division become more and more obviously artificial when applied to them. The function of "the college" in their case becomes intertwined with other func-

tions, technical, professional and scientific! Is such intertwining, is such overlapping and interlacing of functions unwholesome? I think not. I myself welcome the union of technical studies with those which involve a more general cultivation. Men grow so differently, mature at such unequal rates, are cultivated by such different sorts of work, and can use their general cultivation, if they have any, for such various technical purposes, that, for my part I suppose one of the notable functions of an academic institution to be the uniting rather than the further sundering of the various more or less learned activities of modern life, the humanizing of engineers, and the preparation of the young followers of the humanities for some practical service of mankind.

Whatever the functions of "the college" then, it is impossible to treat these functions so as sharply to sunder them from the functions of technical schools. We ought not to say to any one separate class of young men: You want cultivation. That is good. We will therefore give you four years of pure cultivation. Thereafter you shall be ready to undertake something else, which is not cultivation but is your life-work. There are indeed some men who are best trained in just this way. But there are also very various sorts of men in whose cases the most different kinds and degrees of union of technical with non-technical types of training form the best means of education. Our undergraduate instruction must reckon with these various sorts of men. We must offer to them various intermediate kinds of education. And we need to have these various sorts of men kept in social relation with one another as they mature. The fortunes of "the college" must not be sundered from those of the technical schools. And this is what the state universities have taught us.

Equally impossible it is to keep asunder, as some theorists wish to do, collegiate instruction and what is called graduate professional instruction. I have for years heard colleagues of mine protest against permitting instruction which they regarded as professional in its nature to count towards a college degree. I have never been able to get from these colleagues any general definition of what, in the modern world, constitutes the distinguishing mark of a professional study. Of course there are professions, notably law and medicine, which can draw their own sharp lines between their particular professional studies and all non-professional studies. These professions wisely begin their training at a definite point, preferably no doubt with college graduates. But then these particular professions are concerned with topics, and with a sort of technique, which can be begun only when the student has a fairly definable degree of maturity. You can not make a young boy a nurse, and you can not wisely begin to give him early clinical instruction. Fragments of legal lore, introduced into undergraduate instruction, tend, we are told, rather to hinder than to help the later work of the law school. So here sharp lines can be authoritatively drawn. But in modern life there are many professions, and, in case of some of these, the boy can already do what it will be almost necessary for the future professional man to have done as early as possible. I was once told by an old sea-captain that an essential part of his life's training was learned in his sailboat, in the harbor at home, when he was a boy, and that he therefore wholly doubted the power of even the best modern naval training school to make a trustworthy ship's officer out of anybody who had not begun to learn the sailor's trade in early boyhood. I need not say that my captain was not alone in this con-

viction, which is that of the old fashioned mariners generally. But what is true of sailors is in various degrees true of other callings. Good engineers can well be made by a training that begins in boyhood, and that certainly ought to include undergraduate training as well as graduate training. And yet I am sure that an engineer ought, amongst other things, to be as cultivated a man as he can be made, and so I am sure that, in his undergraduate days he ought to have an opportunity for various sorts of cultivation that you and I would agree in calling collegiate. Future teachers, future social workers and clergymen, coming civil servants or colonial officials, embryo scientific investigators of all sorts—all these need, during their undergraduate years, training such that nobody can rationally distinguish between that portion of this training which is professional in nature and that portion of it which is apt to add to their general cultivation. Is training in the use of good English a professional study? I know many workers in various professions—contributors, let us say to scientific journals—who would be much better men in their own profession, because decidedly clearer in their wits, in case they had been better trained as school boys and as undergraduates in the accurate use of plain English. Yet what study could be mentioned that is a more typical instance of a so-called culture-study?

I insist then that one can not in any general way distinguish between the educational offices of technical and professional studies on the one hand, and the studies productive of cultivation upon the other. I myself, for instance, ought to teach logic so as to make it professionally useful to future engineers and to future clergymen alike, and to any cultivated man as well, in case he can be induced to be for a while reflective. If I can not do so, that is my

defect as a teacher of logic. It is useless to condemn me to the vague task of simply so teaching logic as to exert a cultivating influence over people who have no trade and who have not yet chosen a profession. As a teacher of logic I ought to be required to appeal to anybody who chooses to try the value of my personal appeal to him, whether he is a professional student or a technician, a graduate or an undergraduate.

In a college then, we ought to offer the youth such learning and such training as may prove to be useful in fitting men of their age for the life that they are going to lead, in so far as that is indeed a life which involves intellectual training at all, and in so far as they are youth who are mentally and morally fit to be taught during those years of their life. The unfit, the stubbornly unwilling, the unworthy, we must reject or dismiss. But whosoever will may come, if only the secondary schools have made him fit for a grade of training which experience shows to be in general adapted to reasonably normal folk at his age. And when we get him we ought to make him work as hard as is good for him, and not a whit harder than is good for him, at whatever study will best fit him for his life, whether that proves to be a technical or a so-called professional study or not. Of course we must try to add to his technique general cultivation, of the richest sort that we can get him to assimilate. We can best succeed in that if we teachers keep together ourselves, and unite in one institution the work of very various sorts of scientific and of learned men. Hence, while we shall indeed differentiate more and more our professional and technical schools and modes of training, we college teachers do ill if we unnecessarily separate ourselves and our work from close touch with those of our colleagues whose tasks are more technical and professional than are our own. Only

by union with such teachers can we keep the college near to life.

As to our present condition, in the American college of to-day, I agree with our critics that many college boys do not now work hard enough. The remedy lies, of course, in giving such boys more good work to do, and in employing more instructors whose duty it should be to follow them up personally in their work. The remedy also lies in increasing the effectiveness of our systems of individual advice—in brief in individualizing our methods of dealing with the individual. The remedy does not lie in banishing the work of the investigators to separate institutions, nor in differentiating a colony of pedagogical neuters, who can not generate ideas, nor add to knowledge, but who, as one imagines, can therefore the better teach. We have enough of the barren and unproductive minds at present amongst our college teachers. We want more living and growing investigators than we have. And we want our productive investigators to do more undergraduate teaching than they do. There is a place in the college, of course, for the great teacher who can impart knowledge, but who can not add to it, if indeed his is not really an unproductive mind, but a mind that, like that of Socrates, the prince of teachers, produces indirectly, by acting as the midwife, and by delivering others of the ideas with which their own minds are pregnant. But every effort to separate even this singularly valuable class of teachers from their investigating and originating colleagues, or to keep the investigators as a class by themselves, in institutions to be called universities, and to be sundered from our present colleges—every such effort, I say, seems to me to be in the direction of regression, of pedantry, and if I may speak frankly, of obscurantism. We want teaching and investigation to become more and more what

they ought to be—one and inseparable. Some investigators indeed can wisely teach only advanced pupils. Let them confine themselves to such work. Some good college teachers add nothing notable to knowledge. We welcome them whenever they do sufficiently good work of their own kind to make them valuable for the college. Some professional training, by reason of its topic or of its grade, must keep itself well apart from more elementary instruction; let it then do so. But let us not be so terrified by mere names and definitions that we shall set off by itself, in unprofitable isolation from the college, that sort and grade of professional instruction which can also help to awaken and to discipline youth at the collegiate age. And above all let us not be so much the slaves of the mere name *college* as to undertake to draw a sharp line which, in modern life, has no longer a place—a sharp line between all sorts of undergraduate and all sorts of graduate instruction. Many of our graduates need cultivation, badly enough, as all of us know. Many of our undergraduates need pretty advanced studies to wake them up. Let such have them.

As for the unquestionable present evils of too little hard work and too much sport on the part of the college undergraduates of to-day, let us meet these evils in two ways:

1. In general, let us seek to assimilate college work more rather than less to that sort and grade of professional work which calls out a young man's energies just because he feels that in such work something is at stake that is, for him, personally momentous.

2. In detail, let us make the college boy work harder by giving him more work to do, by following him up more closely and individually, and to that end, let us employ more teachers whose work of instruc-

tion shall be individual and personal. Let us abate the evils of sport by fearlessly excluding the mob from our intercollegiate contests, and by rigidly limiting the number of those contests.

In any case, however, let us beware of those theorists who, in the name of what they call the American college, want to sunder afresh what the whole course of our modern American development has wisely tended to join, namely, teaching and investigation, the more technical training and the more general cultivation of our youth, as well as the graduate and the undergraduate types of study. I should abhor the name college if this mere name ever led us into such a backward course as some are now advocating.

Let me say, in conclusion, that, in agreement with Mr. Flexner, I myself believe that a large reform of our relations to the secondary schools, and especially an essential change in our method of college entrance requirements and examinations is called for by the present conditions. But over that whole topic, for my poor wits, the clouds of mystery still hang thick. I leave the matter, and all these now uttered prejudices of mine to the judgment of those who appear to think that they know.

JOSIAH ROYCE

AMERICAN COLLEGE EDUCATION AND LIFE¹

THERE is evidently a feeling in the minds of the public that there is something the matter with our colleges. The more sensitive and alert educational authorities are likewise aware of certain defects, although they may not agree upon the causes. The more or less definite feeling is that college work on the one hand lacks intellectual seriousness, and on the other fails, somehow, to connect vitally with the

present needs of society. Questions as to the length of the course, or the threatened partition of the college between secondary school on the one hand, and the professional schools, including the graduate school, on the other, are really subordinate to this broader question of seriousness and connection. If the college is really worth while we shall doubtless manage the external organization of our system so as to secure its continuance. If the conviction becomes general that it is a survival from the past rather than a useful institution for the present, the really vigorous and ambitious young men will pass it by, and the public will not care to maintain it for the benefit of those who wish merely to spend four pleasant years.

The two chief questions, I conceive, are the value of its intellectual ideals and methods, and the value of its corporate or social life at a certain period in the development of young men and women. I shall confine myself chiefly to the former, in the belief that the intellectual problem needs to be attacked first. The present paper aims to show (1) that the work of the colleges up to about twenty-five or thirty years ago fitted the social situation in both ideal and method; (2) that in the past three decades there has come to be a gap between theory and practise to which the colleges are only in part adjusted; and (3) that the solution is likely to lie through a reconstruction of the college ideal of liberal education under the influence of new vocational methods and ideals. In return we may hope for a gradual permeation of vocations and social institutions by the new spirit and method, which will complete the readjustment between college and life.

1. THE FORMER IDEAL AND METHOD OF COLLEGE AND OF LIFE

The intellectual ideal of the college has

¹ An address given before the Section of Education at the Baltimore meeting of the American Association for the Advancement of Science.

been that of a "liberal culture." This formerly meant three things: As contrasted with studies pursued for utilitarian ends solely or chiefly, it meant genuine intellectual interest. As contrasted with studies determined by the external requirements of future vocation, it meant study directed by the inner, personal valuations, aptitudes, or desires of the scholar himself. In both these respects it meant "liberation," and freedom—freedom for the life of the spirit as over against external necessities or constraints. And in the third place, as predominantly classical, it gave a glimpse of another and different civilization. To the boy or girl brought up in the meager and isolated environment of New England hills or pioneer farm it opened a vista. It gave the æsthetic value of detachment. Some of finer temper caught the full inspiration of converse and companionship with the great minds they came to know. In this sense it was really humanizing. And for ordering one's life and measuring life's values, how could one better gain a point of view from which to see life steadily and whole than in the perspective of the best that had been thought and said?

Now this general scheme of freedom and individualistic literary culture fitted admirably the religious, political and social ideals. For protestantism was religious individualism. Governments were supposed to exist to protect individuals in their natural rights. With practical economic equality, and in a rural, independent mode of life, freedom from external constraint seemed to be the chief social good. And as regards utilitarian demands, in spite of the hard conditions under which life was often led, it was a tradition from early colonial days which had not failed of reinforcement that man's life did not consist in his possessions.

The prevailing method of classical

study, and of the mathematics and philosophy that went along with it, was also strikingly adapted to the professional training and general social order of the period. For the three professions for which the college prepared were occupied chiefly in deducing the consequences from fixed first principles. Systematic theology or grammatical exegesis was the minister's task in the seminary. The statutes, on the one hand, and past decisions on the other, with some fundamental conceptions of natural rights, were the fixed datum of the lawyer. The physician might be less certain of his ultimate principles, but whether "regular" or "homeopathic," his method was about as dogmatic; and as for society, its social, political and moral standards and categories were all supposed to be established. Even the movement for the abolition of slavery needed only the familiar conceptions of rights and freedom. The moral standards could still be regarded as unchanged. The scriptures and the Declaration of Independence could be appealed to, and although some went so far as to denounce the Constitution, American society as a whole strove rather to make its attitude seem to accord with the Constitution than to admit frankly that social needs had outgrown the Constitution. "Legal fiction," through which the courts like to preserve the semblance of fixed principles, could probably never have been taken so seriously, even by the law itself, if it had not suited on the whole the conservative temper of American society. On the one hand, therefore, the learned professions, on the other, society as a whole, had a relatively fixed system.

How admirably the classical and mathematical method of the time prepared the student for such a scheme of fixed conceptions! Syntax and prosody presented a perfect system, a logical whole, which

needed not to be investigated, but to be learned and applied. The future theologian learned respect for authority as he searched the scriptures of Hadley and Goodwin, or Liddell and Scott. In the statutes and decisions of Harkness the future disciple of Blackstone gained practice in tracing subjunctive or dative back to its constitutional rights and limitations. To watch for agreement in gender, number and case, remains, I am told by legal educators, an unmatched training for legal procedure. Finally, Euclid's axioms were the favorite symbol for the supposedly fixed rules of eternal right which every good citizen should learn to respect and obey. If there was any doubt as to this fixity the course in philosophy was calculated to remove it.

This exact adaptation of the method of college to the methods of the professions seems to account, in part at least, for the results achieved in the way of efficient training. It was maintained and the claim need not here be challenged, that the old college training gave power and effectiveness. Modern experimentation has tended to discredit the abstract conception of "power," gained once for all by some hard study, and then applied to any task that presents itself. But the old training was not isolated or in a vacuum. It was about as near the whole habit of mind and technique of method which later life would employ as anything that could be devised. It was thus essentially, although unconsciously, vocational in method, while "liberal" in ideal.

Both in its intellectual ideal of liberal or free culture, and in its method of instruction the college was therefore well fitted for its former place in American society. No wonder that the educational creator pronounced it all very good. And so long as the Sabbath Day lasted the system was beyond criticism.

II. THE PRESENT SITUATION

The variety of subjects now offered, and the elective system as the method of determining the student's course, are in part due to the activity of science in organizing new materials. With the wealth of resources offered by the natural and social sciences and by modern literatures it seemed impossible to restrict access to the city of the elect to the single straight and narrow path formerly followed. There must be gates on four sides instead of on one. But there has also been a social factor in the change, even if it has not always been consciously recognized.

Economic and social expansion has increased greatly the number of occupations for which trained intelligence is needed. Technical schools have arisen in partial answer to this demand, but the college has made its responses also through its variety of subjects with its freedom of individual selection. The progress of science, as represented especially in the graduate school, has no doubt in many cases given to subjects a specialized mode of treatment which is as technical in its way as the method which any professional school pursues. This apparently suits well the needs of one of the new vocations for which the college has come to be a preparation—that of the teacher. The young women who have come to form so large a part of our college constituency, and who for the most part have been looking forward to teaching, have found their needs well met. But for other occupations, especially for non-professional life, no such vocational connection has been worked out. Studies have become individualistic and detached in a far greater degree than was true of the old curriculum, which was really, though unconsciously, vocational.

But economic and social expansion has had another consequence for the college. It has increased greatly the number of

persons financially able to enjoy the best opportunities available. And whatever the attraction which literature or science may have for some of these intrinsically, or whatever the value a college degree may assume as a mark of social distinction, the real standard of value generated by this whole process, as Professor Sumner has pointed out, is that of "success." The studies of the college course seem to bear little relation to this ideal.

And this leads us to a broader statement. The fixed ideals and standards of the older society, which kept men in their place and held them to their work, have broken down. The churches are feeling the same difficulty. Men are largely absent from the pews. They, or at least many of them, are not taking the churches seriously. Many in former days were kept in the church by the general ideals of the community, and so in college many who had no absorbing interest in the work for its own sake nevertheless yielded to the spirit of college and society, and worked under the general idea that the discipline of the college course was validated in a superior law. Such students no longer feel any external pressure. Serious-minded men are groping for new conceptions in religion, economics, politics and law. But these have not been thoroughly enough worked out as yet to replace the old fixed control. Not only the flippant, but the earnest are more or less at sea as to standards and values. As Mr. Crothers puts it, even "the way of the benefactor is hard."

Some, indeed, seem to feel fairly well satisfied with the situation. President Eliot in his recent work on University Administration has a good deal of faith in the present system if there is a proper intrinsic relation maintained between courses, supplemented by a judicious arrangement of the time schedule. Some colleges have

changed their schedules so as to require residence at the week end from those students who had fallen into the habit of spending their leisure half week in neighboring cities. But such considerations, as well as reports like that of the Harvard Committee, and the frank statements of students themselves, point to a real defect. Some would attribute the difficulty entirely to the presence of a frivolous class. But this is evasive. Many, if not most, even of this class, settle down to hard work the moment they enter business or a professional school. And even those who are not on principle averse to anything like strenuous effort feel a certain unreality in the whole situation. There seems to be not only the attitude of "detachment" belonging to the older conception of "liberal" education, but also an attitude which the aestheticians call "make-believe." Now detachment, or even make-believe, may be valuable as a factor in developing a broader, deeper interest, and a more significant, richer purpose. But four years of make-believe seems to be overworking this factor. The young men themselves are coming to think so, and the public at large, while taught to respect the wisdom of its educational experts, is beginning to ask questions.

III. SUGGESTIONS TOWARD READJUSTMENT

The general line along which remedy is to be sought for the present lack of seriousness and lack of connection seems to be *a reconstruction of the college ideal of liberal culture*. This promises to be brought about by a greater introduction of the vocational element and spirit into college work. And this introduction of the vocational into the liberal is being made possible and desirable because *the vocational is being itself permeated and transformed by the liberal*.

The reason for the old-time sharp oppo-

sition of the liberal to the utilitarian and professional was, as we have noted, to protect the intellectual interest and keep the self free from alien constraint or narrow bounds prescribed by vocational conditions. But a new face has been put upon this situation by the development which is going on in the industries and occupations, and in some, at least, of the learned professions. For the various occupations are being organized more and more along scientific lines; they are becoming permeated with intellectual and æsthetic interest; they demand of themselves a wider reach and stimulate a broader survey. In so far as they do this they break down the distinction between the liberal and the vocational. Not the way in which knowledge is to be used—much less the fact that it is not used at all—but the method and spirit in which it is pursued on the one hand, and its breadth of human interest on the other, make it liberal. Any study is liberal, if pursued in a scientific manner and given significance for human life. Such studies call out a widening self. In such studies the mind comes to its own. In such it gains power. In such it is no longer determined by needs or conditions foreign to itself. Rather it is using these needs and conditions as the most effective instruments for asserting itself.

Medicine is perhaps the farthest advanced of the professions in this respect. And the college studies pursued by the future teacher, which are professional so far as their future use makes studies professional, show the absurdity of the old distinction on the basis of utility, or non-utility. For Latin or mathematics as pursued by the future teacher of these subjects is probably more liberalizing than when pursued by those who do not expect to make use of them.

Nor has the process of permeating vocations with scientific interest stopped with

the so-called professions. Modern commerce and industry involve the use of intelligence in ways that are properly scientific. And there is no reason why, if studied in their historic development and in their bearing on human welfare, they may not call out as broad and as human an interest as any other field of human activity.

This mutual permeation of the vocations by the scientific and of the liberal by the practical looks, indeed, toward a more effective and positive type of "freedom" than the older conception of the more romantic and negative sort, which sharply opposed the interests of the self to the sphere of its action. The older freedom from constraint corresponded to the formal freedom which was so important an element in political and religious liberty, and which was so prominent an ideal in the last of the eighteenth and during most of the nineteenth centuries. The courts by their distinction between law and fact, which tends to prevent the contamination of legal doctrine by recognition of actual conditions, maintain this theoretical freedom as a basis in many of their decisions. But social and economic facts emphasize that it is positive resources which give the only freedom that amounts to anything. Psychological analysis shows that only as the mind has both ideas and positive control of its instruments is it free in any considerable degree. The student is then free of his world, is fitted to lead a free life, is having a liberal education, in proportion as he is getting such control of the instruments of knowledge and such efficiency in dealing with his fellow men as makes him master not merely of his ideas, his emotions and his purposes, but of his world. The old individualism in education, as in religion, was largely to lose or hold off from the world in order to save the soul by culture.

The new scientific and social situation demands, and in increasing degree will make it possible, that the educated man shall control his world. And in so doing he will save himself. When this conception is embodied in the college there will be no lack of seriousness.

When the colleges have made their work once more a genuine and serious preparation for the new social situation they will be able to give society in turn the aid it needs in changing from the old fixed conceptions, and finding a new type of social order—an order that shall make larger provision for progress. This help, I believe, is to come through the influence of the newer experimental method which largely under the influence of our graduate study is coming to leaven the best work in all subjects. It has its fitness for our new conditions as conspicuously as the older method fitted the conditions of a relatively fixed status.

The laboratory method of studying the sciences began to gain ground in the colleges at about the same time as the introduction of the elective system. It has been strongly reenforced by historical or genetic conceptions given prominence by the doctrine of evolution. Although still very imperfectly carried out, it is replacing more and more the scheme of fixed conceptions and deduction from established rules which constituted the older syntactical, mathematical and moral systems. If this can be carried over into professional conceptions and social organization there will be once more a close connection between the college and society. Medicine and philanthropy have already made notable progress. Theology and religion are feeling the need of reconstruction. The courts are perhaps necessarily the most conservative elements—unless possibly we except schools and colleges—but when legal education has felt fully the

force of genetic study we may expect that both criminal and civil justice will consider in greater degree actual human and social conditions in controlling human relations.

And if the established professions need a new method to enable them to fulfill their vocation in the society that is to be, business and industry need the aid of scientific method and standards to make them professional in the true sense. Considering these occupations as non-professional, we have left them no test for the success that every normal man wishes to secure, but that of economic gain. And since economic gain may result either from service or from exploitation, our educational theory and training have lent no such powerful support to the conception of public service through one's vocation as the scientific standards of law, medicine and teaching afford members of those professions. As President Eliot has pointed out, this purely financial standard has not proved a conspicuous success even from the standpoint of efficient management of business enterprise. Is it not desirable that education should try to introduce other and more scientific standards? And is it too high-flying an optimism to hope that the time may come when it will be considered as unprofessional to manage a country's industries or transportation or banking with an eye principally to financial gain as it now is to practise medicine with such a standard of success? The scientific and the ethical here go hand in hand.

The professional schools themselves are not likely to embody this method in its full significance in their work. The function of the college intellectually is to make this the dominant temper of the student.

And the second intellectual function of the college is to give material for the future citizen. First of all, he must know

society. The social sciences ought to be strongly developed. But training for a democratic society is not limited to a peculiar subject. Nothing human is foreign to the purpose of the college. But it is a fair question whether literary study may not be for the college less an end in itself and more an avenue through which one comes to know and sympathize with all sorts and conditions of men. And even the natural sciences need not hesitate to let their bearing on human welfare appear.

An experimental method and a social standpoint are, I conceive, the two respects in which the college should perform its office of liberal training in a way suited to our new conditions.

In view of the fact that women now form so large an element in our colleges, it may be permitted to point out some special applications of these considerations to woman's education on the one hand, and to the determination of woman's place in the social order on the other.

College education for women has thus far followed essentially the lines laid down by the general system already in vogue. "Equal opportunity" was the watchword at first, and it is probable that any differentiation in kind might have been regarded as involving inferiority in standard or value. "Woman's work" is still, it must be confessed, often treated by the world in general as implying a depreciatory estimate. As already noticed, a large number of women, looking forward to the occupation of teaching, have found the existing courses largely vocational. For this, or other reasons, the lack of intellectual seriousness has thus far not been so much in evidence as with the men. But as an increasingly larger proportion of the women students will not become teachers, the question of connection between college work and after life is likely to become more acute. The need for introducing

into college more material of a vocational sort, and conversely of permeating woman's vocational work of all kinds with a scientific method and a broadly human interest, is likely to become increasingly evident. The work of the woman in the home has lagged far behind the occupations of men in point of organization and of the use of scientific method. An educated woman is apt to feel, vaguely, that the whole household life—once the center of all the industries, and the place where discovery and invention had their chief seat—has now been left behind in the progress of civilization and is no longer a field for the exercise of intellectual powers of the highest order. This inevitably tends to depreciation of such occupation, and to strain in the family life.

Some would find the remedy by purely sentimental and emotional exaltation of home life. They would in effect continue the separation between the scientific spirit and the home. Is it not more promising to work, rather, along the lines suggested in the case of men's vocations, and try to liberalize women's vocations by scientific methods and a more broadly human standpoint? It is not yet sufficiently recognized, for example, that in modern city life the home is virtually coterminous with the city. The sanitation, the food supply, the health of the home are now dependent on municipal conditions; the education of the children, the influences that surround them, the ideals that influence them are reached chiefly by forces that are civic and philanthropic in a broad sense, rather than domestic in the narrow sense. And further, while the organization of production, the conduct of litigation, and various other traditional vocations are likely to remain predominantly in the hands of men, it is increasingly apparent that as wealth increases beyond provision for bare necessities woman becomes the more im-

portant factor in determining the course of consumption. Vocational training for woman will then be conceived broadly enough to enable her to plan not only economically, but with taste and refinement for those satisfactions that are permanent and genuine, and also with intelligent judgment for those that make for the larger social welfare.

And the final application of the experimental method in this connection lies just in the determination of what women's vocations are ultimately to be. The older society had no doubts. The religious, economic, political and social status of woman could all be deduced with perfect exactness. It was as easy as the agreement of a verb with its subject. The present equilibrium is unstable. Is it not a scientific method to work out the problem with careful reference to the new conditions as they emerge, rather than to decide by past history or fixed conceptions?

In conclusion I may barely hint at a question which no doubt arises as to the bearing of this whole discussion on the college as a distinct organization. If professional education is to become liberalized, what need of the college? And if the spirit of investigation is the main factor, why again the college? Why not the university joined directly to the secondary school? In the long run I think this is likely to depend on the need of a factor which has been barely referred to above. Effective education depends in part on a scientific factor, but there is also a personal factor. One must know his fellows and how to cooperate with them. This is increasingly important with the growing complexity of society. And this efficiency in dealing with others is not easily secured in professional or graduate school where the emphasis is on subject and method, and the life is individualistic. If the college can maintain a corporate life in which

knowledge is vitalized, in which there is actual give and take, actual sympathy and friction, active interchange not only between mind and mind but between will and will, then it will find its own place, and live secure.

JAMES H. TUFTS

UNIVERSITY OF CHICAGO

THE PROPOSED HAWAIIAN MEETING IN 1910

THE action taken by the general committee of the American Association for the Advancement of Science at the Baltimore meeting in again unanimously re-affirming a resolution adopted at the Chicago meeting of a year ago to the effect that it was desirable to hold a meeting of the association in Honolulu during the summer of 1910, provided suitable arrangements can be made, is quite generally regarded as a flattering acceptance of Hawaii's cordial and urgent invitation.

All Hawaii is united in the desire that their invitation be extended to each of the individual members of the American Association for the Advancement of Science, and of the affiliated societies, and to their families and friends. Keen delight is expressed at the prospect of welcoming the scientific men of America to the "Land of the Heart's Desire," for such a meeting and outing. Hawaii is prepared and willing to do all in its power to make the meeting a large, notable and important gathering not only of the scientific men of America but of the other countries that border on or have possessions in the Pacific Ocean. To this end elaborate preparations are being made for the entertainment of all who may attend.

A strong local committee has already been formed. They have printed and ready for general distribution a number of pamphlets setting forth the things prospective visitors will want to know about Hawaii. The probable cost of the trip from the east will not necessarily exceed \$300. An especial booklet emphasizing the desirability and advantages of Honolulu as a summer meeting place and the things of interest to be seen by the scien-

tific visitors in the island was especially prepared for distribution at the Baltimore meeting. Those who desire the literature or wish information about the trip or are in any way interested in the meeting are requested to address Mr. Albert F. Judd, Secretary Hawaii Committee, Judd Building, Honolulu, H. I.

It is desired that you state to the committee the particular subject that interests you most that detailed information may be sent you thereon. The farther advantages of having your name and address will be that it will enable the local committee to keep you informed of special rates and other matters of interest to those contemplating the journey. It is desirable at the present time to secure the assurance of your interest, the matter of coming can await further consideration.

WM. ALANSON BRYAN

SCIENTIFIC NOTES AND NEWS

THE meeting of the Chicago Academy of Sciences on February 23 was in honor of Charles Darwin. Professor C. O. Whitman, of the University of Chicago, gave an address on "Some of the Principles of Organic Evolution as revealed in the Pigeon World."

THE Rochester Academy of Science held on February 22 a meeting in commemoration of the Darwin centennial. Addresses were made by Professor C. W. Dodge, on the life and work of Darwin; by Professor H. L. Fairchild, on Darwin and geology; and by Professor W. D. Merrill, on Darwin and botany. An exhibition was made of material illustrating evolution.

WE learn from *Nature* that at the meeting of the Royal Society on February 18, telegrams of congratulation on the hundredth anniversary of the birth of Charles Darwin were read from the University of Christiania, the University, Kharkoff, the Naturalists Students Association, Kharkoff, the Society of Naturalists, Kharkoff, the council of lecturers, Moscow Women's University and the Swedish Academy of Sciences, Stockholm. The president reported that telegraphic acknowledgments and thanks had been trans-

mitted to the senders on behalf of the Royal Society.

A MEETING of the Leeds Naturalists' Club was held on February 15 to celebrate the Darwin centenary, when Mr. Harold Wager, F.R.S., delivered an address on the life and work of Darwin.

M. H. POINCARÉ has been elected president of the French Bureau des Longitudes.

THE University of Liverpool will confer its doctorate of laws on Mr. William Marconi; its doctorate of science on Mr. Francis Darwin and Mr. J. L. Todd and its doctorate of engineering on the Hon. C. A. Parsons.

THE universities of Oxford and of Cambridge have conferred the degree of D.Sc. on Dr. Sven Hedin.

THE seventieth birthday of Dr. G. Lunge, professor of chemistry at Zurich, will be celebrated on September 15.

DR. DAVID STARR JORDAN, president of the American Association for the Advancement of Science, has appointed the following committee to inquire into the manner and course of publication, distribution and use of publications, of American scientific societies: Franz Boas, chairman; R. S. Woodward; William Trelease; J. McK. Cattell; E. G. Conklin.

MR. A. L. BOWMAN is chairman of a special committee appointed by the American Society of Civil Engineers "to consider and report upon the design, ultimate strength and safe working values of steel columns and struts."

MR. JOHN C. OSTRUP, professor of structural engineering at the Stevens Institute of Technology, has been elected a member of the Institution of Civil Engineers of Great Britain.

MR. W. F. BATTERSBY, of the School of Mines, Kingston, Ontario, has won the prize of one hundred dollars which was offered by Mr. J. B. Tyrrell, of Toronto, for the best collection of minerals made in the Province of Ontario during the past year.

PROFESSOR W. M. DAVIS, of Harvard University, now serving as professor in the University of Berlin, has conducted a geological

excursion of some sixty students through the Wera and Leine Valleys.

SIR RUBERT BOYCE, F.R.S., dean of the Liverpool School of Tropical Medicine, is on behalf of the Colonial Office visiting the West Indies for the purpose of looking into the present methods of dealing with sickness and recommending what can be done to promote the physical welfare of the people.

THE Yale Chapter of Sigma Xi held its annual banquet February 27, following the initiation of the new members. Dr. W. N. Rice, professor of geology at Wesleyan University and holder of the first doctor's degree awarded by Yale for study in geology, delivered the formal address of the evening. He spoke on "The Return to Faith," discussing the newer relation of science to religion. Other speakers were Professor Ross G. Harrison; Professor William Hallock, of Columbia University; Professor Charles W. Brown, of Brown University; Assistant Professor R. C. Hawley, '04F., Davenport Hocker, '08, and F. L. Gates, '09.

At the meeting of the Chicago Section of the American Mathematical Society, the following officers were elected: G. A. Miller, University of Illinois, *chairman*; H. E. Slaught, University of Chicago, *secretary*; O. D. Kellogg, University of Missouri, *member of the program committee*. The next meeting of the section will be held at the University of Chicago on April 10 and 11.

At the annual meeting of the Physical Society, London, the following officers were elected: *President*, Dr. C. Chree; *vice-presidents*, those who have filled the office of president, together with Mr. W. Duddell, Professor A. Schuster, Mr. S. Skinner and Dr. W. Watson; *secretaries*, Mr. W. R. Cooper and Dr. S. W. J. Smith; *foreign secretary*, Professor S. P. Thompson; *treasurer*, Professor H. L. Callendar; *librarian*, Dr. W. Watson.

At the anniversary meeting of the Geological Society of London, the officers were elected as follows: *President*, Professor W. J. Sollas; *vice-presidents*, Mr. G. W. Lamplugh, Mr. H. W. Monckton, Dr. J. J. H. Teall and

Professor W. W. Watts; *secretaries*, Professor E. J. Garwood and Dr. A. Smith Woodward; *foreign secretary*, Sir Archibald Geikie; *treasurer*, Dr. Aubrey Strahan.

THE Congress on Tropical Diseases, which was opened at Bombay on February 22, was attended by representatives of all parts of India and by Major Ronald Ross, of Liverpool, Professor Shiga, of Japan, and Dr. Musgrave, of the Philippines. The congress is accompanied by a popular medical exhibition.

DR. FREDERICK W. TAYLOR, past-president of the American Society of Mechanical Engineers, gave an address before the College of Engineering of the University of Illinois on February 18.

PROFESSOR CHARLES L. EDWARDS, of Trinity College, will address the Scientific Society of Stamford, Conn., on March 12, on the subject of "The Methods and Results of Deep-sea Exploration."

DR. GEORGE GRANT MACCURDY, of Yale University, gave a lecture before the Buffalo Society of Natural Sciences on February 28, his subject being "The Ancient Art of Chiriqui."

A MEMORIAL has just been erected in Kensington Cemetery, London, to the memory of Admiral Sir Francis Leopold McClintock, the Arctic explorer and discoverer of the lost Franklin expedition. It takes the form of an old style wheel cross standing on a massive molded base, reaching to a height of 10 feet and executed in rough silver-gray Cornish granite.

DR. JAMES W. MOORE, professor of physics in Lafayette College since 1872, died on February 28, at the age of sixty-four years.

SIR GEORGE KING, F.R.S., eminent for his researches on the flora of India, died on February 13, at the age of sixty-eight years.

DR. DAVID JAMES HAMILTON, lately professor of pathology at Aberdeen University and eminent as a pathologist, died on February 19, in Aberdeen, at the age of 60.

A GOVERNMENT laboratory of bacteriology has been founded in Warsaw. The director is Dr. Tscharnozky. The laboratory is in-

tended chiefly for the purposes of veterinary and public health researches.

THE University of Heidelberg has received from a foreign benefactor interested in the advancement of science the sum of over \$30,000 towards the foundation of a radiographic institute.

DR. FRANCIS ELGAR, F.R.S., the naval architect, who died on January 17, aged sixty-three, left an estate of the value of £80,000. The testator left £1,600 to the Institution of Naval Architects for the endowment of a scholarship. After making other bequests, he left half of the residue of his property (which will apparently amount to about £33,000), subject to the interest of his wife during widowhood, as to one half to the Institution of Naval Architects for the encouragement of the science and art of naval architecture, and one half to the University of Glasgow, to be held upon trust for the furtherance of the objects of the John Elder chair of naval architecture in that university.

A BALLOT of the proprietors of the London Institution on the proposed amalgamation with the Royal Society of Arts has been taken and resulted as follows: For amalgamation, 322; against, 218. The proprietors, of whom there are 850, were asked to say whether they approved of the drafting of an act of parliament for the amalgamation of the two institutions on the lines of the scheme which was drawn up by the joint committee in 1905. In a preliminary postcard poll 524 voted in favor of the proposal and only 84 against it.

OFFICIAL information has been received by the U. S. Bureau of Education at Washington that an International Musical Congress will be held at Vienna at the end of May, 1909, in connection with the centennial celebration of the birth of Josef Haydn, the composer. A desire has been expressed that the United States should be represented in this congress.

AN International Exhibition of Hygiene will be held at Turin during September, October and November.

WE learn from the *British Medical Journal* that the second International Conference on

Leprosy will be held this year at Bergen from August 16 to 19. The preliminary program includes the following subjects: The geographical distribution of leprosy; the forms and diagnosis of the disease; its causes and manner of propagation; its pathological anatomy, and its treatment. The conference will be held under the patronage of the Norwegian Government and King Haakon. The president will be Dr. G. Armauer Hansen, discoverer of the *Bacillus lepræ*. The vice-president is Professor C. Boeck, of the University of Christiania, another recognized authority on leprosy. The secretary is Dr. H. P. Lie, of Bergen, to whom all communications relative to the congress should be addressed.

WE learn from the *London Times* that at a meeting of the joint organizing committee of the International Congress of Applied Chemistry, held in the rooms of the Chemical Society at Burlington House, the secretary presented a report giving details of the progress made since the last meeting of the committee in June, 1908. It was stated that £4,400 had been received in response to a special appeal issued in December. The government was stated to be considering the question of defraying the cost of the South Kensington group of buildings, belonging to the University of London, for the meetings of the congress. Several members of the government have accepted the offices of honorary vice-presidents of the congress, including Lord Morley (Secretary of State for India) and Mr. Haldane (Secretary of State for War). The Society of Chemical Industry, which numbers over 4,000 members, has arranged to hold its annual meeting for 1909 in London on May 26, the day preceding that of the opening of the congress, and the London members of this society have also arranged to entertain the members of the congress on the evening of May 29. Foreign and colonial governments, and the leading scientific and technical societies, have been asked to appoint delegates to represent them at the congress. These delegates will rank as honorary and as ordinary members of the congress respectively.

UNIVERSITY AND EDUCATIONAL NEWS

By action of the corporation the chair of the theory and practise of medicine at Yale University will hereafter be known as the John Slade Ely professorship of the theory and practise of medicine. This action was made possible by the gift to the university of \$50,000 by an unknown donor for the purpose of establishing a memorial to Professor Ely, '81S., who filled this chair from 1897 until his death, February 7, 1906. Dr. George Blumer at present holds this professorship.

It is announced that Hamilton College will receive a bequest of \$50,000 from Mrs. Annie P. Burgess, of New York City, who died about three years ago, leaving for educational and charitable purposes upward of \$200,000. This included \$10,000 to Columbia University and to Barnard College for scholarships. After making some other specific bequests she left the remainder of her estate to Hamilton College, Columbia University and Barnard College.

AMONG the bequests left by the late Mrs. Emma Cummings, of East Hampton, L. I., are \$25,000 to Dartmouth College and \$25,000 to Bowdoin College.

THE late Dr. Charles H. Roberts, of Highland, N. J., in his will provided for the founding of five scholarships of \$240 annually at Cornell University.

HARVARD UNIVERSITY has received a gift of \$150,000 for the endowment of the University Chapel. The fund is to be known as the Edward Wigglesworth Memorial Fund.

MARYVILLE COLLEGE, Tennessee, has secured an endowment of \$227,000, of which \$50,000 is from the General Educational Board and \$50,000 from Mr. Andrew Carnegie.

THE University of Michigan has acquired by gift of an alumnus, and from the city of Ann Arbor, a tract of land of about ninety acres to serve as a botanical garden and arboretum. This land has an exceptional variety of soil, elevation and exposure, including a border of over one half mile on the Huron River, easily accessible from the

campus. The Woman's League of the university has purchased a seven-acre tract of land, convenient of access, which will be developed as an athletic field for the women of the university. Another gift is of about fifteen hundred acres of land, lying along the shores of Douglas lake in Cheboygan county. This land will serve as the site for the summer engineering camp, and its topography, including forest and open, land and water, various elevations, etc., is well adapted to the purpose. In honor of the donor it has been named The Bogardus Engineering Camp.

MRS. S. T. ROBINSON, of Lawrence, Kansas, is offering an opportunity to all women who graduate from the science department of the University of Kansas to do research work in connection with the research table supported by her in the Marine Biological Laboratory at Woods Hole.

THE Russian government has decided to establish a new university at Saratoff, and the duty of organizing it has been entrusted to Dr. Rasumowsky, professor of surgery at Kasan.

GOVERNOR DRAPER, of Massachusetts, has appointed Mr. Frederick P. Fish, of Brookline, to be a member of the State Board of Education, to succeed the late Carroll D. Wright. Mr. Fish is a member of the board of overseers of Harvard College and a member of the corporation and executive committee of the Massachusetts Institute of Technology.

DISCUSSION AND CORRESPONDENCE

THE MISSISSIPPI CHANNEL BOTTOM AND GULF LEVEL

TO THE EDITOR OF SCIENCE: The remarkably slight elevation above the sea of the lower flood plains of large rivers like the Mississippi, the Ganges and the Amazon is a matter of frequent comment. The facts are often put rather strikingly by saying that at St. Louis, 1,250 miles by river from the sea, the valley flat is but 400 feet above sea level; at Memphis, 842 miles from the sea, 220 feet; and at Vicksburg, 472 miles from the sea, 90 feet. The same fact is commonly expressed

in terms of the gradient of the river. The Mississippi has a gradient of a few inches per mile from Cairo to the gulf; while the Amazon, rapidly aggrading its flood plain and still quite under the dominion of the waste delivered to it, has, according to the best barometric determinations, an average gradient for the last 500 miles of only one eighth of an inch per mile!¹ Barometric determinations are notably unreliable, but errors are at a minimum near sea level in the tropics and this value may be taken as indicative of at least the order of magnitude of the river gradient. The Nile has now been carefully measured by an almost complete line of leveling from Victoria Nyanza to the Mediterranean, a distance of 3,500 miles. It offers a similar set of conditions in its flattest part between Sorbat and Khartum, where the slope has been reliably determined to be from one half to one third of an inch per mile.² More striking is the statement of elevation in terms of channel bottom: "the bottom of the channel of the Mississippi is as much as 100 feet below the level of the gulf some 20 miles above New Orleans."

It occurred to the writers that in the case of the Mississippi a possibly still more striking form of expression is that which refers the elevations of channel bottom to sea level, thus arriving at an upstream point where the plane of sea level intersects the channel bottom. The distance of this intersection from the sea or the river mouth is a very striking value indeed. The detailed results of our map examination are expressed in the following table which is compiled from the charts of the Mississippi River Commission based on the surveys of the period 1879-1884. The table shows the maximum depressions and elevations of the channel bottom that occur on each

chart, the location of each point (referred to a station usually near some town or landing), together with its distance from the gulf. It will be observed that the first upstream point at which the channel bottom attains gulf level is 388 miles by river from the gulf. The most northerly point at which the bottom

Chart No.	Maximum Elevation of Channel Bottom above Gulf Level*	Minimum Elevation of Channel Bottom above Gulf Level*	Location	Miles from Gulf (Cairo = 1972)

THE NAMING OF NEW SPECIES

TO THE EDITOR OF SCIENCE: The volume of *Proceedings* of the United States National Museum for 1908 has just come to hand with its usual wealth of zoological literature, much of which is naturally of a systematic character. As I have looked through the various articles, and have noted the large number of new species described, I have been struck by the very considerable proportion of names given "in honor of" somebody, or derived from a geographical or geological locality. In other words, the percentage of specific names which are in any sense descriptive or suggestive to a fellow-worker in the same group, is very small, and I am therefore moved to call the attention of systematic zoologists (including, of course, the paleontologists) to what seems to me a very unfortunate tendency among us. The naming of an animal "in honor of" some one has much to recommend it from the personal point of view, if we agree not to debate the question whether it is an honor to have a parasitic worm, a skunk or some other unlovable creature named in one's honor. But from the scientific point of view, the custom of using personal names for the designation of particular animals has little to commend it, except possibly where the name of some preeminently great master of a field may be perpetuated in connection with the group upon which he worked; something may be said in favor of *darwini* as the name of a cirriped. The use of names derived from localities or geological horizons has more to recommend it, for such names may be, and often are, suggestive and distinctive. But they are very apt to be shown, by further advances of knowledge, to be not only inapplicable, but oftentimes misleading, and they should only be used where there is little chance for blunders. It seems to me a great pity that we can not return to the original idea for a specific name, that it should be in some sense descriptive. Of course it must be admitted that many names of this class are very misleading, but that fact should only make us more careful in the selection of the names we give. Many zoologists do not real-

ize what the situation really is and I therefore wish to give an analysis of the papers in the volume of *Proceedings* before me.

There are 30 articles in which new species are described, 24 of which deal wholly with recent, and 6 with fossil, species. In the thirty articles 223 new names are proposed for species, besides a number of varieties and subspecies which I have left out of the account. Of the 223 names, 130, or 58 per cent., are in some degree descriptive; 47, or 21 per cent., are names of persons; 45, or nearly 21 per cent., are locality names, and 1 is of doubtful significance.

Of course the 130 names are not all equally descriptive, some are very doubtfully so. The 45 locality names include names derived from geological horizons. The 47 names of persons include 40 individuals, one of whom is honored (?) no less than three times. When it is realized that this honor (?) is sometimes actually asked for, directly or indirectly, it may be seen how very dubious it is. Of the forty individuals, I can count but nine whose scientific attainments can fairly be said to warrant their being chosen; others, of course, would differ from me in the count, but I think no one would find twenty.

Among the thirty papers, some are notably free from the evils I am pointing out. Mr. A. H. Clark's papers on Crinoidea include 29 names, of which at least 86 per cent. are descriptive (the derivation of *komachi* is beyond me, so I have not called it descriptive) and Mr. William Warren's paper on geometrid moths includes 84 names of which 94 per cent. are descriptive. Deducting these papers, we find that of 160 names, 73, or less than 46 per cent., are descriptive; 43, or 27 per cent., are personal, and 44, or more than 27 per cent., are locality names.

But Professor Nutting's report on Hawaiian Alcyonaria includes 38 names, of which nearly 77 per cent. are descriptive (8 are personal), and if we deduct these names, we find that of the remaining 122 names, 44, or only 36 per cent., are descriptive; 35, or 28½ per cent., are personal, and 43, or 35½ per cent., are locality names.

Examination of the remaining papers reveals the fact that the paleontological writers pay the least attention to descriptive names, for in their six papers, we find that of 59 proposed specific names 5, or less than 10 per cent., are descriptive; 23, or 38 per cent., are personal, and 31, or over 52 per cent., are locality names.

It would be uncharitable, if it were not quite uncalled for, to suggest either of the two most obvious reasons why an author, particularly a young or inexperienced writer, selects personal or locality names for his new species. But I can not avoid the feeling that these reasons occur to our fellow workers in the other fields of zoology, and may have something to do with the feeling, which it is often said they hold, that we systematists are engaged in a lower grade of work than that with which they are occupied.

THE 6-INCH TRANSIT CIRCLE OF THE U. S. NAVAL OBSERVATORY

TO THE EDITOR OF SCIENCE: The following paragraph, which is an essential feature of a paper read by me before Section A, American Association for the Advancement of Science, in Baltimore on December 28, 1908, has been omitted from the abstract of that paper printed in SCIENCE for January 22, p. 154:

"It having been found that the instrument had suffered some damage from gradual deterioration during the five years that it had been out of use, the axis tube and circles and various other parts were sent to Warner & Swasey for repairs with a view to put the instrument in condition to do the fundamental work for which it was originally intended. This work is now nearly finished and the axis and some other parts of the instrument have been returned to the observatory. The pivots have been reground with great care, and elaborate tests have shown them to be very regular in shape and so nearly equal in size that the difference is inappreciable. It is

hoped that the remaining parts of the instrument will be returned to us in a few days, in which case measures will be taken immediately to mount the instrument and commence the work of investigation and observation."

SCIENTIFIC BOOKS

Resultats du voyage du S. Y. Belgica en 1897, 1898, 1899, sous the commandement de A. de Gerlache de Gomery. Rapports Scientifiques. *Oceanography*, par HENRYK ARCTOWSKI et HUGH ROBERT MILL, 1908. *Physique du Globe*, mesures pendulaires, par G. LECOINTE, 1907. *Zoologie: Turbellarien*, von LUDWIG BÖHMIG, 1908. *Scaphopoden*, von L. PLATE, 1908. *Pennatuliden*, von HECTOR F. E. JUNGENSEN, 1907. *Cirripedia*, by P. P. C. HOEK, 1907. *Geologie: Glaciers*, par HENRYK ARCTOWSKI, 1908.

The reports of the *Belgica* expedition continue to appear, each adding to our knowledge of the Antarctic, its conditions or its fauna. The numbers of which the titles are summarized above are not less interesting than those which preceded them. Space permits but a brief account of their contents.

The soundings and aërial temperatures of the sea water taken by the *Belgica* were the first in that region to be observed and corrected by the most modern instruments and methods. Two conclusions are of especial interest. The observations showed that the deeper waters of the Atlantic and Pacific are practically separated by submarine ridges which, extending from the southern end of the American continent to the Antarctic lands, present a barrier to the free circulation of the waters in question. Secondly, it is proved that the surface water of the sea is cooled by the low Antarctic air-temperatures and by floating and melting ice, below which is a warmer stratum which reaches its maximum temperature two or three hundred fathoms below the surface, after which the temperature gradually diminishes until the bottom of the sea is reached. The persistency of the warmer stratum indicates the slowness of changes due to convection, and the existence of currents

by which the warmer waters from the north replace the colder upper stratum which moves from the south. The temperatures naturally have a very narrow range, comprised within ten degrees of the point (28° F.) where sea water freezes.

The report on the pendulum observations is preceded by a short and pathetic account of the life and services of Lieutenant E. Danco, who died on the *Belgica*, at the age of twenty-nine years and to whom these observations had been confided. A fine portrait of Danco accompanies the notice. The work was carried on subsequently by Lecointe, but owing to a variety of circumstances the value of gravity was obtained by the expedition only at Punta Arenas in the Straits of Magellan.

In his discussion of the glaciers and bergs Arctowski considers first those of Tierra del Fuego, and secondly those of Gerlache Bay and the Antarctic lands. He concludes that the mountainous region of both was once continuous, the geology indicating much the same characteristics. He also contrasts the effect of the ice cap where incomplete and broken by nunataks, and when existing as a continuous covering extending to the sea level. In the latter case and for Antarctica generally he is disposed to believe that the ice is exercising a comparatively small abrasive function, and that its effect on the subjacent rock is very slight at present, the glacial streams being clear instead of milky and rock forms exposed by the retreating ice rounded off rather than channeled or excavated. This memoir is illustrated by numerous excellent half-tone plates derived from photographs.

The report on the barnacles considers a few Magellanic forms and one new truly Antarctic species, *Verruca mitra*, obtained in some 250 fathoms in south latitude 70°. Only one strictly Antarctic species was previously known, the *Scalpellum antarcticum* Hoek, obtained by the *Challenger*.

Only one species of Pennatulidæ was obtained on the expedition. This belongs to the genus *Umbellula* first described from the Polar Sea by Ellis from a dry specimen obtained in 1758. The *Belgica* species is *U. carpenteri* K  lliker, first obtained by the *Challenger*.

Two other species are known from the Antarctic, of which one is so close to the Arctic *U. encrinus* of Linn   as to be regarded by K  lliker as the same species.

Only two scaphopods were recognized by Plate in the collection, from south of latitude 70° S. One is referred to the *Dentalium majorinum* of Mabille and Rochebrune, variety *gaussianum*, previously described from material obtained by the Gauss expedition. The other, though probably a distinct species, was not sufficiently perfect for description.

The turbellarians comprised a new genus and species of Acoela, *Rimicola glacialis* B  hmig, and three species of Tricladida, of which one, *Procerodes hallezi*, is described as new. The latter is Fuegian, having been dredged in Beagle Channel. A new genus and subfamily are described to include *Procerodes* (now *Stummeria*) *marginata* Haller. The forms discussed are anatomically described and figured in great detail.

WM. H. DALL

A Text-book of Mechanical Drawing and Elementary Machine Design. By JOHN S. REID, Professor of Mechanical Drawing and Designing, Armour Institute, and DAVID REID, formerly Instructor in Mechanical Drawing and Designing, Sibley College, Cornell University. Revised edition, enlarged. Pp. xi + 433. New York, John Wiley & Sons. 1908.

It would be difficult, in fact practically impossible, to compress within equal limits more of service to the student of machine design who wished at the same time to qualify as a draftsman. Not only are all necessary proportions and tables given for the designing of screws, nuts, bolts, keys, cotters and gibs, riveted joints, shafting, pipes and couplings, bearings, belt and toothed gearing, valves and general engine details, but there are also full data for drafting courses, with the unusual feature of time-allotment included, securing the early attainment by the novice of a commercial rate of speed in his work.

As indicative of the methods and procedure in one of the leading technical schools the book is of especial interest to teachers of

drafting; while the student who must, by force of circumstances, be self-instructed, could not be better provided therefor.

The treatment of valve-motion is admirable. The precedence given the Bilgram diagram over the Zeuner, although unusual, is fully warranted, the former being far superior for designing, while possessing equal merits with the latter for analysis.

The frequent shaded perspectives will be especially appreciated by the beginner in machine drawing, obviating, as they do, in considerable degree, the necessity for the models recommended but not always obtainable.

Among the more important features appearing for the first time in this edition are the "Course in Lettering" and the "Present Practise in Drafting Room Methods," the latter a summary of replies, from two hundred of the leading engineering firms of this country, to thirty-five questions as to shop practise. An ample index completes this altogether valuable work.

A POSSIBLE ERROR IN THE ESTIMATES OF THE RATE OF GEOLOGIC DENUDATION¹

THE presentation at the Baltimore meeting of the American Chemical Society of a paper by Dole and Stabler on the rapidity of geologic denudation recalls attention to a possible source of error in such estimates which has been already implied in the writings of Walther, Udden and other students of æolian geology. The peculiarly thorough and comprehensive figures of Dole and Stabler are deduced, as have been all previous ones, from the examination of river waters, and are based upon the assumption that all material which is removed from the land to the sea is carried in suspension or solution by outward-flowing water. Recent studies on the magnitude of æolian transport cast some doubt upon the validity of this assumption. It has become apparent that much surface material is moved from place to place by æolian action and that much of this transport is to be ascribed to the slow and unnoticed, but continuous, action of

¹ Published by permission of the Secretary of Agriculture.

ordinary winds. The winds are so ubiquitous and so incessantly in motion that their aggregate geologic work is by no means negligible, though it may be momentarily inappreciable. If the winds are constantly carrying material they must be carrying some of it to sea, and of this the major part will be deposited in the ocean and only a small fraction returned to the land. Land breezes are notoriously dusty, and that the winds blowing inward from the ocean are much more free from solid contamination is known, not only deductively and from general observation, but as the result of actual counts of the dust particles.*

Udden¹ has calculated on very conservative data that the transport capacity of the winds blowing outward from the Mississippi Basin is at least one thousand times greater than that of the river. This, of course, refers only to transport *capacity*, and no one imagines that the actual amounts of material moved are in the same ratio. The air, unlike the water, is seldom loaded to any considerable fraction of its capacity. It is evident, however, that if the wind performs only an infinitesimal part of the carriage for which it has the ability, its activity is nevertheless far too great to be neglected. Neither is the Mississippi Basin a region especially susceptible to æolian action. The immense amount of wind-borne material carried out of deserts is universally admitted, and the example of the sirocco dust which constantly leaves the Sahara for the Atlantic to the west and the Mediterranean to the north is universally familiar.

From the information at present available it is entirely impossible to estimate with accuracy the yearly rate of æolian removal or the resultant error in the calculations of the rapidity of denudation. It seems, however, not improbable that the error is of some moment and that the present estimates are too low in a not unimportant degree, even when their admittedly approximate character is taken into account. These conclusions derive added force from two recent papers by

* Aitkin, *Trans. Roy. Soc. Edinb.*, 42: 486, 1902.

¹ *Jour. Geol.*, 2: 318-331, 1894.

Thoulet² in which he records his conviction that a considerable fraction of the mud of the sea bottom is terrestrial dust borne to its position by winds and fallen through the overlying water in an approximately vertical path.

BUREAU OF SOILS,

U. S. DEPARTMENT OF AGRICULTURE

THE AMERICAN SOCIETY OF ZOOLOGISTS

THE regular triennial joint meeting of the Eastern and Central Branches of the American Society of Zoologists was held at the Johns Hopkins University, Baltimore, Md., on December 29, 30 and 31, 1908.

The following resolutions were adopted:

Resolved, That this society most urgently recommends to the Committee on Ways and Means, or other body having the matter in charge, that the present duty on scientific books published in English, and on scientific apparatus be removed.

Resolved, That, in the opinion of this society, the migratory birds of the United States should be properly protected by national laws, and that this society urges immediate consideration of the bill, introduced by Representative Weeks, now before Congress.

The officers elected were:

EASTERN BRANCH

President—Herbert S. Jennings, Johns Hopkins University.

Vice-president—H. V. Wilson, University of North Carolina.

Secretary-Treasurer—Lorande Loss Woodruff, Yale University.

Additional Member of Executive Committee—Maynard M. Metcalf, Oberlin College.

CENTRAL BRANCH

President—Edward A. Birge, University of Wisconsin.

Vice-president—Michael F. Guyer, University of Cincinnati.

Secretary-Treasurer—Charles Zeleny, University of Indiana.

The following papers were presented:

Diverse Races of Paramecium and their Relation to Selection and to Conjugation: H. S. JENNINGS, Johns Hopkins University.

² *Comptes Rendus*, 146: 1184-1186, 1346-1349, 1908.

"Wild" cultures of *Paramecium* were found to consist of many diverse races, which remain constant in relative mean size when propagated in "pure lines," by fission. Eight such differing "pure lines" were isolated and propagated side by side under the same conditions for many months. The smallest race had a mean length below 100 microns; the largest a mean length above 200 microns. Most existing races fall into two groups: (1) those with mean length above 170 microns; (2) those with mean below 140 microns. The former group corresponds to what has been described as the species *caudatum*, the latter to *aurelia*. A single race falling half-way between the two groups was found; such races are rare.

Within the pure race there is much variation due to environmental conditions and to growth, but such variations are not inherited. Large and small individuals of the same race produce progeny of the same mean size, so that the characteristics of the progeny depend on the fundamental constitution of the race, not on the individual peculiarities of the parent. It is not possible to produce by long continued selection diverse races from a single race.

The diverse races retain their relative sizes throughout the life cycle, including conjugation. Owing to the assortative mating described by Pearl, there is a tendency for the diverse races to remain isolated even when conjugation occurs.

The Reactions of *Didinium nasutum* with Special Reference to the Feeding Habits and the Functions of *Trichocysts*: S. O. MAST, Woman's College of Baltimore.

Light Reactions in *Euglena* and *Stentor coeruleus*: S. O. MAST, Woman's College of Baltimore.

Notes on *Opalina*: MAYNARD M. METCALF, Oberlin College.

A paper describing the phenomena to which these notes refer will appear in the *Archiv f. Protistenkunde*, Bd. XIII., Heft 3.

The Measurement of Relative Toxicity and of Differences of Physiological State by the Use of Protozoa: A. W. PETERS, University of Illinois.

Selection of Food in *Stentor coeruleus*: ASA A. SCHAEFFER, Johns Hopkins University.

From a capillary pipette, potato starch grains, particles of sand, bits of debris, *Euglena viridis*, *Phaous triquetus*, *Trachelomonas volvocina*, etc., were fed in mixed order, on to the disk of a *Stentor*. The path and fate of each particle was recorded. The starch, sand and debris were al-

most invariably rejected, while the organisms, either freshly killed or living, were invariably ingested. When the *Stentor* became more and more filled up, more and more of the organisms were rejected, until eventually all organisms, as well as all starch, sand, etc., were rejected.

In some experiments it was shown that some organisms are eaten while others are not; thus in a stream of *Euglena viridis* and *Trachelomonas volvocina*, fed in mixed order, although both kinds of organisms were eaten at the beginning of the experiment, the *Stentor* ate only *Euglena* in the latter part of the experiment, rejecting all *Trachelomonas* and also some *Euglena*.

Thus *Stentor* can "select" food particles from a stream containing food and non-food particles. Further, *Stentor* can "select" one kind of food from a mixture of several different kinds, such as *Euglena* from *Trachelomonas*, etc.; and it is highly probable that *Stentor*, when nearly replete, "selects" certain individuals to the exclusion of others, of the same species.

Selection can be explained upon purely objective grounds as determined by the action of the stimulus in the particle upon the ingesting mechanism (including the varying physiologic state) of *Stentor*.

Duration of the Cycle of *Paramecium*: LORANDE LOSS WOODBURN, Yale University.

A culture of *Paramecium* has been carried on a varied culture medium for twenty months, during which time 930 generations have been attained. Conjugation has been prevented by the daily isolation of individuals, and no artificial stimulation has been employed. "Abnormal" physiological or morphological changes have not appeared in the specimens.

Effects of Centrifugal Force on the Organization and Development of the Eggs of Ascidians and Mollusks: E. G. CONKLIN, Princeton University.

The Organization of the Egg of a Medusa: E. G. CONKLIN, Princeton University.

The Oogenesis of *Cumingia telkinoides* (Conrad): H. E. JORDAN, University of Virginia.

The primary oocyte at the beginning of the growth period has a nucleus of three microns diameter. The nuclear reticulum is achromatic except for a large eccentric nucleolus. At slightly later stages chromatic masses appear in the nucleus and are generally arranged in pairs. Such pairs probably represent presynaptic bivalent chromosomes. The arrangement of the chromosomes indicates parasynapsis. Still later in the

growth period the chromosomes become aggregated into a mass and the latter assumes a more or less close connection with the nucleolus. Both nucleolus and chromosome-mass are typically close to the nuclear wall. Maturation proceeds to the metaphase in the ovarian egg. A single instance was observed where the mitosis had passed to anaphase. The later phases of maturation occur only after the egg is extruded and fertilized. The nucleolus disappears during the metaphase of the first maturation mitosis. It seems to contribute a small amount of chromatin to the chromosomes, after which its main bulk is reabsorbed by the cytoplasm. The nucleolus appears to be of the nature of reserve food material rather than a waste product.

The astral system of the first mitosis consists of a large, very chromatic centrosome surrounded by a homogeneous acropasmic centrosphere which is bounded by a "microsome circle" and an outlying astrosphere. Between metaphase and anaphase in the free eggs the centrosome disappears. The centrosphere of the second polar spindle, as also of the fertilization and early segmentation spindles, is achromatic and granular. The centrosome appears to be merely an accompaniment of the astral system, representing a transient metabolic phase of maturation coincident with the formation of the first polar spindle. The reduced number of chromosomes is eighteen. The second mitosis segments univalent chromosomes transversely and is the reducing division.

The Germ-cell Determinants of Chrysomelid Beetles: R. W. HEGNER, University of Michigan.

The Germ-cell Determinants.—This paper is based on the study of the lineage of the germ-cells of *Calligrapha multipunctata* and three other chrysomelid beetles. At the time of laying a disc-shaped mass of granules is present at the posterior end of the egg suspended in the peripheral layer of cytoplasm. I have called this disc the "pole-disc" and the granules the "germ-cell determinants." The cleavage products in the eggs of these beetles migrate through the central yolk mass to the periphery, where they produce the blastoderm. Those cleavage products that come in contact with the germ-cell determinants do not produce blastoderm cells, but continue their migration until they are entirely separated from the egg. These cells take with them practically all of the germ-cell determinants. At first there are 16 of these cells, but they soon divide twice, the final number being 64. These are the primordial germ-

cells. They can be traced back into the embryo, where by amoeboid movements they migrate half to either side of the germ-band. Later they produce the germ-glands. The sexes can be distinguished during the embryonic period by the shape of the germ-glands.

The Results of Removing the Germ-cell Determinants.—A number of fresh eggs were punctured and the germ-cell determinants allowed to flow out. These eggs developed into embryos or larvae which contained no germ-cells.

The Sexual Differences of the Chromosome Groups in Pyrrhochoris and Syromastes: EDMUND B. WILSON, Columbia University.

The facts in *Pyrrhochoris* and *Syromastes* have been supposed to contradict the general rule, established for many other forms, that those spermatozoa which receive the accessory chromosome are female-producing, the others male-producing; for in both cases the two sexes have been described as having the same number of chromosomes—24 in *Pyrrhochoris* and 22 in *Syromastes*. A reexamination of both sexes in the two forms has proved that they form no exception to the rule, previously published accounts being erroneous in respect to the male of *Pyrrhochoris* and the female of *Syromastes*.

In *Pyrrhochoris* the male number is not 24, but 23, the odd or accessory chromosome being the largest of the chromosomes. Half the spermatozoa receive this chromosome and half fail to receive it, the former class having 12 chromosomes and the latter 11. The female groups contain 24 chromosomes, of which two are of the same relative size as the single accessory of the male. *Pyrrhochoris*, therefore, conforms precisely to the usual type shown in *Anasa*, *Protenor*, etc.

In *Syromastes* the male number is 22 (as described by Gross), but the female number is not 22, but 24, as was first inferred by the writer from the condition seen in the male only. Direct observation has now proved that this inference was correct. *Syromastes* constitutes a new type in which there are two accessory chromosomes (the second and third smallest of the spermatogonial groups) which pass together, as a bivalent, into half the spermatozoa. These spermatozoa receive 12 chromosomes, the others 10, and the somatic numbers of the sexes prove that the former class are female-producing, the latter male-producing. (Demonstrations by photographs.)

Some New Types of Chromosome Distribution and Their Relation to Sex: FERNANDUS PAYNE, Columbia University.

A study of *Gelastocoris* and the Reduviidae has revealed several new types of chromosome distribution.

There is present in *Diplodus* and several other species of the Reduviidae a pair of idiochromosomes, which in the new types is replaced by a compound group. Each of these groups as a whole behaves as a pair of idiochromosomes, the small idiochromosome being represented by one element and the large idiochromosome by a multiple group. In *Pitohia* the multiple group consists of two; in *Prionidius*, three; in *Gelastocoris*, four; and in *Acholla multispinosa* (identified by E. P. Van Dusee) of five chromosomes. This multiple group in the second maturation division always passes to one pole and the single element the other, thus producing in each case two classes of spermatozoa.

The male and female chromosome groups are, respectively, 27 and 28 in *Pitohia*; 26 and 28 in *Prionidius*; 35 and 38 in *Gelastocoris*; and 26 and 30 in *Acholla*. Judging from these numerical relations the two classes of spermatozoa must be male and female producing.

It seems very probable that the new types have arisen from the idiochromosome type by the large idiochromosome breaking up into a number of elements.

These new types of chromosome distribution offer nothing new to the theory of sex-production as advocated by Wilson ('06) and Stevens ('06), but they are perfectly consistent with it.

In *Acholla multispinosa*, although the female has the larger number of chromosomes, the male seems to have the greater quantity of chromatin.

See Determination and Parthenogenesis in Phyllocera and Aphids: T. H. MORGAN, Columbia University. (See *Science*, 1909.)

Maturation, Fertilization and Cleavage of Tubularia crocea and Pennaria tiarella: GEO. T. HASEGATA.

During the period between the end of the growth of the egg and the formation of the polar bodies the large nucleolus disappears, a concentration of the chromatin occurs, the nucleus decreases in size and becomes ovoid in shape. At the pointed outer end only, in the nucleus of *Tubularia*, an aster without a centrosome is usually present for a considerable time. The fate of this aster is not known.

Polar bodies are formed by mitosis. No asters or centrosomes are present in the first polar spindle, so far the only one actually observed. In *Tubularia* two polar bodies are formed. In the

first polar spindle of *Pennaria* apparently only about one half of the somatic number of chromosomes is present, though the actual number is still uncertain. In *Pennaria* the time of formation of the polar bodies varies considerably, some eggs passing through this stage just before fertilization, and some several hours before the liberation of the eggs from the medusae.

In *Pennaria* spermatozoa may enter the egg at any point, though usually close to the position of the egg nucleus. The transformation into the sperm nucleus takes place just within the edge of the egg, before migration toward the egg nucleus begins. One or both of the pronuclei are often multi-vesiculate, at least up to the time of conjugation. No asters or radiations of any sort are present during the conjugation of the pronuclei.

Segmentation seems to be always by mitosis and cytoplasmic division is often delayed until several nuclei are present.

Early Development of the Spider's Egg: THOS. H. MONTGOMERY, JR.

The gastrulation takes place from an anterior and a posterior cumulus, and from the margins of the germ disc; vitellocytes form at all these regions, mesoblast and entoblast only from the anterior cumulus. The vitellocytes take no part in producing the intestine. Entoblast develops only in the abdomen. The blood cells arise from the extraembryonic ectoblast, and migrate secondarily into the embryo. One pair of coelomic sacs develops anterior to the mouth, and the rostral prominences are to be considered prestomial appendages of this head segment; there is no evidence of other preoral appendages. Pulmonary lamellae appear before the pulmonary appendages invaginate, and upon these. The supraesophageal ganglion is a fusion of one pair of cerebral ridges, and a pair of antero-lateral and a pair of postero-lateral vesicles, all local differentiations of the single head lobe.

The Formation of the Mouth Opening and the Limits of the Ectoderm and Entoderm in the Mouth of Amphibians: J. B. JOHNSTON.

The Post-anal Gut and its Relation to the Doctrine of Recapitulation: BASHFORD DEAN, Columbia University.

It was pointed out that the general value of the "biogenetic law," now often discredited, might be tested by paleontological documents, even in the case of structures whose nature rendered them poor subjects for fossilization. This Dr. Dean illustrated in the case of the post-anal gut in the embryos of fishes, giving reasons to show that the post-

anal was a functional gut in the adult of certain Devonian sharks. In these forms (Cladodactylids) the anal fin was paired, its elements converging at the base of the tail, where the cloaca was accordingly located. The sub-caudal position of the cloaca is, moreover, indicated by the position of the kidneys. These are now known, both by macroscopic and histological characters in these fossils to have continued behind the ventral fins and converged near the tail.

The Cause of Pulsation in Scyphomedusæ: ALFRED GOLDSBOROUGH MAYER, Carnegie Institution of Washington.

In the case of *Cassiopea samachana* the sodium chloride of the sea water is a powerful stimulant to the nervous system, but its tendency in this direction is exactly offset and counteracted by the inhibiting influences of the magnesium, calcium and potassium. Thus the sea water as a whole is a balanced fluid, and neither stimulates nor inhibits the pulsation of the medusa.

The stimulus which causes pulsation is due to a slight but constantly maintained excess of sodium chloride over and above its concentration in the sea water. This excess of sodium chloride is engendered in the distal endodermal cells of the marginal sense-organs, which constantly give rise to sodium oxalate. This oxalate precipitates the calcium chloride and sulphate which enter the sense-club from the surrounding sea water, and forms the calcic oxalate crystals of the sense-club, thus setting free sodium chloride and sulphate, which act as powerful nervous stimulants to which the nervous elements respond periodically.

The stimulus-producing pulsation is thus wholly internal, not due to external agencies. It has been commonly supposed that the crystalline concretions in the sense-clubs of scyphomedusæ were calcium carbonate, but I find upon chemical analysis that they are oxalates.

The Sense of Hearing in the Dogfish: G. H. PARKER, Harvard University.

If the side of a large wooden aquarium in which a dogfish (*Mustelus canis*) is swimming quietly is struck a vigorous blow, the dogfish will react by a quivering motion, especially of the posterior edges of the pectoral fins. By the use of a heavy pendulum the momentum with which a given blow was struck could be determined. The momentum of the minimum blow to which normal fishes reacted was arbitrarily called unity. After the eighth nerves were cut a blow with a momentum three or four times that just mentioned was needed to produce a reaction. This response was

believed to be due to the mechanical stimulation of the skin. After the skin of a normal fish had been rendered insensitive by cutting the fifth, seventh and lateral line nerves, and by encasing the pectoral regions, a step not taken in previous experiments, the fish was found to be as sensitive to sounds as a normal fish is. This sensitiveness entirely disappeared when in addition to the operations already carried out on the fish, the eighth nerves were cut. Sounds affect both the skin and the ears of the dogfish and the latter organs are the more sensitive of the two.

Regulation in the Morphogenetic Activity of the Oviduct of the Hen: RAYMOND PEARL, Maine Agricultural Experiment Station.

This paper gives an account of a case in which a gradual change in the shape of eggs successively laid by the same bird occurred. This change in the shape of the eggs is (1) referable to a change in the activity of the oviduct, (2) definitely progressive and (3) regulatory in character, since it proceeds from the abnormal to the normal. The first egg laid by a particular Barred Plymouth Rock pullet (No. 183) was strikingly abnormal in shape (long and narrow). Every egg laid by this bird was saved and measured. As eggs were successively laid there was a gradual change in shape from the abnormal condition found in the first eggs to a substantially normal condition.

The change in the shape of the eggs was found to follow a logarithmic curve, of the type seen in growth curves.

The Nature of the Stimulus which Causes a Shell to be Formed on a Bird's Egg: RAYMOND PEARL and FRANK M. SURFACE, Maine Agricultural Experiment Station.

This investigation was undertaken to determine precisely what is the nature of the stimulus which excites the reflex activity of the shell-secreting glands of the oviduct in birds. These possibilities were to be considered:

1. That the stimulus is mechanical, and arises from the presence of a soft body (the egg) within the "uterus" or "shell gland."
2. That the stimulus is chemical in nature.
3. That the activity of the shell-secreting apparatus is controlled directly by the functioning of other parts of the reproductive system.

If shell formation is caused from the mechanical stimulation of the "shell gland" by the egg it would be expected that any foreign body introduced into that portion of the oviduct would have a shell formed around it. It was found to be impossible to introduce a foreign body of any size

from the outside into the "shell gland" without resort to such violent methods as to make the conditions entirely abnormal. Further, the foreign body introduced should approximate to the consistency of the egg, so that the stimulus may be physiological rather than traumatic.

To realize these conditions the following operation was performed on hens. The oviduct was transected 1 or 2 cm. above the upper end of the "shell gland." The anterior portion of the oviduct was then ligated. The intestine was transected just anterior to the cloaca and the cloacal wall repaired by inversion of the stump and a purse string suture. Then the cut end of the intestine was anastomosed to the cut end of the oviduct ("shell gland"). As a result of this operation the feces must necessarily pass through the "shell gland" on the way to the cloaca. *In hens on which this operation has been performed a calcareous shell is deposited on the feces during their passage through the shell gland.* The results obtained from these experiments are held to warrant the following conclusions:

1. The stimulus which sets the shell-secreting glands of the fowl's oviduct into activity is mechanical rather than chemical in nature.
2. The formation of a shell on the hen's egg is brought about by a strictly local reflex, and is not immediately dependent upon the activity of other portions of the reproductive system (nervous impulse of hormone formation).

Experimental Control of Fission in Planaria:
C. M. CHILD, University of Chicago.

The Artificial Production and the Development of One-eyed Monsters: CHARLES R. STOCKARD, Cornell Medical School.

The eggs of the fish, *Fundulus heteroclitus*, give rise to a large percentage of cyclopean embryos when subjected during their development to solutions of magnesium salts in sea water. These one-eyed embryos hatch and many of them swim in a perfectly normal manner, darting back and forth to avoid objects placed in their field of vision as readily as do two-eyed individuals.

The cyclopean fish is entirely comparable to the one-eyed human monsters. Both have a median eye more or less double in structure. The nose in the human cyclops is a proboscis-like mass above the eye. The nasal pits in the "magnesium embryos" are sometimes united and sometimes separate, but the mouth hangs ventrally as a proboscis-like organ, suggesting in form the nose in mammalian cyclopia.

The fish embryos exhibit various degrees of the

cyclopean defect from eyes unusually close together to approximated eyes, double eyes and finally a single median eye. The different conditions are exhibited from the earliest appearance of the optic outpushings and in no case was cyclopia due to a union or fusion of the two eye components after they had originated separately.

A second type of monster, "monstrum monophthalmicum asymmetricum," was also common in the magnesium solutions. These individuals have one perfect eye of the normal pair but the other is either small, poorly represented or entirely absent. This condition is also present from the first appearance of eye structures and is not due to degeneration or arrest of development.

Both types of monsters often form well-differentiated crystalline lenses independently of a stimulus from the optic-cup.

The experiments conclusively prove that developing eggs may be induced to form cyclopean monsters by external influences which do not mechanically injure certain eye regions. Therefore, cyclopean monsters in nature are probably not due to germinal variations, but are far more likely the result of some unusual external influence during development.

Cosmobia; a Theory Concerning Certain Types of Monsters: H. H. WILDER, Smith College.

The readiness with which the types of double monsters may be arranged in related series has been recognized for some time, and this phase of the subject has been recently revived. To illustrate this, the main types of the Janus series were presented, beginning with a symmetrical Janus, passing through the different stages of gnathopagus, thoracopagus, etc., and ending with a type of duplicate twins in which the placenta alone is common, the other parts distinct. This leads to the definition of such twins as double monsters in which the common parts are confined to the extra-embryonal structures. These are lost at birth, freeing the components. The diprosopus group was treated in the same way. Attention was then called to the fact that in symmetrical monsters that are less than unity the doubled or compound parts, eyes, limbs, etc., are indistinguishable from those that are found in monsters that are on the other side of the normal, i. e., the diplopagi. As a conclusion from this it seems that both classes of monsters are due to the same or a similar cause, and that normal individuals also belong in the same general series. To such individuals, both less and more than unity, including also normal forms, the term "cosmobia,"

or "orderly beings," may be applied. These forms are held to be due to some fundamental cause inherent in the germ itself, that is, in the egg or the embryo in the early cleavage stages, and must be carefully distinguished from all deformities or other monstrosities that are due to external or later developing causes, not germinal.

A Further Contribution on the Regenerative Power of the Somatic Cells of Sponges after Removal from the Parent: H. V. WILSON, University of North Carolina.

I have described (*Journ. Exper. Zool.*, Vol. V., No. 2) a method by which sponges, more particularly *Microciona*, may be made to regenerate from somatic cells. The sponge is cut into pieces and the pieces are strained under pressure through bolting cloth. The separated cells of the body pass through the pores of the cloth and collect as a sediment on the bottom of the dish. The sediment may be drawn up into a pipette and strewn over a glass slide or other object. The cells combine, forming a plasmodial structure which gradually differentiates into a functional sponge having pores, oscula, flagellated chambers and canals. It remained doubtful whether sponges grown in this way would live long enough to develop the characteristic skeleton. The experiments with *Microciona* have been repeated, and the regenerated sponges kept for two months. The characteristic species-skeleton was differentiated. Reproductive elements and embryos were also formed. The sponges appear to be healthy and to differ in no wise from normal specimens.

The Effects of Certain Paralyzing Agents on Form Regulation: C. M. CHILD, University of Chicago.

The Rate of Regeneration and the Effect of New Tissue on the Old Body: CHARLES R. STOCKARD, Cornell Medical School.

Regeneration takes place equally fast from the disk of *Cassiopea wamachana*, whether it be in periodic pulsation or in a condition of rest.

Peripheral pieces of the disk cut in sundry patterns show decided regulatory ability and tend to assume the original circular shape of the entire disk in the most direct way that their forms will permit. The attainment of the circular form inhibits the process of regeneration in the pieces, yet regeneration will continue for a much longer time if such shapes be prevented.

The rate of regeneration from a peripheral cut on the *Cassiopea* disk is faster the nearer the disk center the cut is made. In the brittle-stars *Ophio-*

coma riisei and *O. echinata* new arms regenerate faster as the old arms are cut off nearer their base of attachment to the body-disk.

The rate of regeneration does not bear a definite relation to the extent of injury in all animal species. The medusa, *Cassiopea*, regenerates each oral-arm at a rate which is independent of the degree of injury when replacing either one, two, four or six of its arms. If, however, eight arms are amputated each arm regenerates at a rate significantly faster than the rate when injured to any less degree. *Ophiocoma riisei* regenerates one, two, three, four or all five of its arms at rates not significantly different. *O. echinata* grows in individual arms fastest when only a single arm is regenerating and successively slower when two, three, four and five arms are being replaced.

Regenerating tissue possesses an excessive capacity for the absorption of nutriment and may do so even to the detriment of the old body tissue. The unfed disk of *Cassiopea* decreases in size in direct relation to the number of regenerating arms. Although the disk regenerating eight new arms is growing them at the most rapid rate, it is, nevertheless, decreasing in size most rapidly. In growing specimens of *Ophiocoma riisei* the increase in size is slower in those individuals regenerating many arms as compared with others regenerating fewer. *O. echinata* regenerates each arm faster when only a few arms are cut, such individuals increase in size at about the same rate as do those which are regenerating each arm slower although more arms are being replaced.

Successive Regenerations; New Observations and General Discussion: CHARLES ZELANTY, University of Indiana.

The Physiology of Nematocysts: O. C. GLASSER and C. M. SPANGLER, University of Michigan.

Nematocysts, isolated by digestion and moderation, can be discharged by raising their internal pressure.

The pressure needed to bring about explosion varies with conditions. It may be artificially altered by immersion in various liquids, a fact which explains why the nematocysts of eolids explode in sea water, whereas those freshly isolated from coelenterates, do not.

When stimulated, the nematocyte is a factor in the discharge of the thread. It is not possible to show that stimulation of the mother-cell results from all the conditions under which explosion occurs. Nevertheless, it is probably true that when a nematocyst discharges as the result of conditions normal to the lives of coelenterates, it

does so because the nematocyte enclosing it has been stimulated.

Elevation of the internal pressure of the nematocyst may be the cause of normal explosion in *calenterrates*. If we suppose that stimulation of the nematocyte inaugurates changes which result in lowering the concentration of the cell contents surrounding the nematocysts, the result can be understood. If, as is not unlikely, heat is liberated, the matter becomes still easier, for either dilution or heat can separately bring about the instantaneous discharge of freshly isolated nematocysts.

Distortion brings about the discharge of isolated nematocysts, but uniform external pressure is useless. It might be supposed that inside the nematocyte there is a mechanism capable of squeezing the nematocyst. Such a mechanism is at present purely hypothetical, and, it seems to me, not needed to explain the facts.

The threads of nematocysts, contrary assertions notwithstanding, are able to penetrate the tissues of other animals, but in order to do so must make their punctures during the period of highest speed, viz., at the beginning of the eversion. This observation renders unnecessary the assumption of a "Reizgift," made in order to account for the nettling sensation produced by nematocysts.

The Behavior of the Cuckoo: FRANCIS H. HERRICK, Western Reserve University.

There is no conclusive evidence to show that the American black and yellow-billed cuckoos are either losing their nesting instincts, or that once having lost them they have been regained. Possibly a lack of attunement of the cyclical instincts occasionally seen in all birds, and rather more frequent in these cuckoos, may have been the starting point of the "parasitic" habit of *Occlus ocnorhynchus* and related old-world genera. Parental instinct is strong in the American cuckoos, and their nests, though frail, are well adapted to their purposes.

The eggs are commonly laid and hatched on alternate days, but nest-life is not unduly prolonged in consequence, this apparent extension being counterbalanced by the development of a remarkable climbing instinct in the young and a premature desertion of the nest. In the life and behavior of the young cuckoo three stages are clearly distinguished: (1) period of infancy, when their black skin is sprinkled with snow-white "hairs" or rudimentary down; (2) complete quill stage on the sixth day and (3) the climbing stage when on the seventh day the nest is sum-

marily deserted by each bird in order of development, and marked by a sudden though incomplete transition to the feather state.

The cuckoo is remarkably enduring from birth, and its grasping reflex most striking. When born it can support its own weight with one foot or with a single toe. Later with feet and bill it easily raises itself upon any support. At the close of the quill-stage fear is present, and there is perfect association with the nest and parent. The feather tubes now begin to give way at their base, especially over the breast and abdomen, and in the energetic practise of the preening instinct the tubes are combed off by the mouthful and in a few hours. The tubes of the flight-feathers and those of the back break away centripetally, so as to expose the shafts gradually as in other birds. When the bird climbs out of the nest early on the seventh day it is only half fledged, quills still showing on head, neck and back. In the climbing stage, when they remain in bushes for upwards of ten days, their behavior suggests that of the young hoatzin.

In serving the large caterpillars and larvae which are brought to the nest by both parents, the insect is placed in the mouth, and not in the throat, as in nearly all birds observed, and is held there for, it may be, five minutes, neither bird moving, or until the swallowing reflex is started. The last bird in the nest is apt to be deserted, parental instinct being diverted and satisfied by the attentions which those already in the bush demand.

Phototaxis in Fiddler Crabs: S. J. HOLMES, University of Wisconsin.

The Reactions of Amphibians to Light: A. S. PEARSE, University of Michigan.

Ten representative species of amphibians were tested and all of them showed marked phototropic reactions. In most instances these species gave the usual responses after the eyes had been removed, the skin serving as a photoreceptor. When a toad was stimulated through only one eye by light from in front or when the skin of an eyeless toad was subjected to unilateral stimulation by light from above, the resulting locomotion was toward the stimulated side and not toward the source of illumination. Such responses are, therefore, brought about by bilateral differences in stimulation and not by any orienting influence due to the direction of the light rays. Previous conditions of light stimulation had no apparent effect on the photic responses of the toad.

Although the rays toward the violet end of the

spectrum produced the largest number of positive responses from normal salientians, no such potency was manifested by the shorter rays when eyeless individuals were tested. In the latter case all rays were equally effective in inducing reactions.

Eyeless toads which gave marked phototropic responses were indifferent to radiant heat of an energy value equivalent to that of the light used. It may, therefore, be affirmed that thermo- and photo-reception are distinct processes in the toad's skin.

Spinal amphibians gave no photic responses, but light reactions were induced in animals which had lost the portions of the brain anterior to the metencephalon.

The Receptiveness of the Vertebrate Skin for Light and the Origin of the Vertebrate Eye:
G. H. PARKER, Harvard University.

In the last few years it has been shown that numerous amphibians will respond to light by moving either toward it or away from it even after their eyes have been removed. The receptive organ in this response is the skin. Tests of a like kind have been made on only a very few fishes. It is highly probable that the skin of *Amphioxus* and of *Fundulus* is not sensitive to light and it is very certain that that of ammocetes is highly sensitive to this stimulus. To ascertain the condition in other fishes, blind individuals of nine species of marine forms were tested by throwing upon the side of the body a beam of concentrated sunlight. The species tested were *Mustelus canis*, *Anguilla chrysypa*, *Fundulus heteroclitus*, *Stenotomus chrysops*, *Tautoglabrus adspersus*, *Tautoga onitis*, *Chilomycterus schaeppi*, *Opsanus tau* and *Microgadus tomcod*. In no instance was any reaction observed. As all these species and *Amphioxus* are marine and the amphibians and ammocetes are inhabitants of fresh water, it seems as though fresh water was favorable for the development of integumentary sensitiveness to light and salt water inimical to this. The condition may be just the reverse of animal phosphorescence which is common in the sea, but unknown in fresh water. If further investigation should prove that no marine vertebrate has an integument sensitive to light, such theories of the origin of the vertebrate eyes as derive it from the skin would be rendered highly improbable.

Methods of Studying Color Vision in Animals:

ROBERT M. YERKES, Harvard University.

There are three general methods of obtaining chromatic stimuli: the reflection method (absorption and reflection by colored papers, cloths, pig-

ments), the transmission method (absorption and transmission by colored glasses, gelatines, solutions) and the refraction method (dispersion spectra by means of prism).

Of these three methods, the first is purely qualitative, and has as its chief recommendation the naturalness of its stimuli. The second method is both qualitative and quantitative, but it fails to give the experimenter that degree of control of the wave-length of his stimulus which is demanded by the thoroughgoing and rigidly scientific quantitative investigation. The third method promises to meet the chief requirements of quantitative work.

These requirements are that the method shall enable the experimenter (1) to obtain stimuli of any desired wave-length or range of wave-lengths, (2) to measure the wave-length of the stimuli accurately and with reasonable facility (preferably by means of a calibrated slit mechanism), (3) to control the intensity of the stimuli perfectly by (a) moving the source of light, or (b) changing the size of the beam, or (c) interrupting the beam, or by each of these methods in turn, (4) to measure the intensity of stimuli accurately and easily both photometrically and radiometrically (preferably by means of a calibrated mechanism), (5) to present chromatic stimuli to his subject independent of the secondary criteria of discrimination: size, form, distance, position, texture of surface and temperature.

Investigations now in progress in the psychological laboratories of Harvard and Johns Hopkins universities, under the direction of the committee on standardization of tests appointed by the American Psychological Association, promise to provide us soon with an admirable method for the study of color vision in animals. A report of the results of these investigations is now in course of preparation by R. M. Yerkes, J. B. Watson and E. D. Congdon.

An Account of Experiments for Determining the Complete Life History of Gasterostomum gracilescens: D. H. TENNENT, Bryn Mawr College.

In previous work¹ the writer demonstrated the life history of *Gasterostomum gracilescens* with the exception of infection of the oyster.

During the summer of 1908 I obtained *Lepistosteus osseus* from the region of oyster beds in Newport River, North Carolina, and found that they contained *Gasterostomum* in abundance. The faces of the fish were found to contain *Gasterostomum* embryos.

¹ *Quart. Jour. Mic. Sci.*, Vol. 49, pp. 635-690.

A mixture of feces in water was injected between the valves of uninfected oysters and these oysters were placed in a wire box in the water. After one month these were taken up and examined. Of twenty-six oysters thus treated twenty-two were alive and contained sporocysts of *Gasterostomum* immediately outside of the stomach wall.

This experiment completes the demonstration of the life history as follows:

1. Adult *Gasterostomum* in *Lepistosteus osseus* and in *Belone vulgaris*.

2. Sporocysts and cercariæ (*Bucephalus*) in the oyster.

3. Free immature and encysted *Gasterostomum* in *Morone* and other small fishes which serve as food for *Lepistosteus* and *Belone*.

The work also indicates the probable identity of *Bucephalus polymorphus*, found in fresh-water mussels, and *Bucephalus haimeanus*, found in various marine lamellibranchs.

Embryonic Variability in Echinoids: D. H. TOWN, Bryn Mawr College.

Study of variations of plutei of same age, but from eggs of different females.

Comparison of fed with unfed plutei.

Study of plutei obtained from eggs of one female which were divided into several portions and each portion fertilized with sperm from a different male.

Variation in the Tentacles of *Hydra viridis*:

ALBERT M. REESE, West Virginia University.

These investigations sought to show (1) the variation in the number of tentacles, (2) the relation between the original number of tentacles and the number regenerated after decapitation and (3) the relation between the number of tentacles of a bud and the number possessed by the parent.

Parke states that the number of tentacles varies from four to eleven; and Rand says that in one hundred and fifty *Hydras* only three had nine tentacles, while about 12 per cent. had eight tentacles.

In the six hundred *Hydras* here studied the tentacles varied in number from four to twelve. Only four individuals with the greater number of tentacles were found. About 54 per cent. of the *Hydras* had eight tentacles, 24 per cent. had seven tentacles, and 15 per cent. had nine tentacles. The other numbers between four and twelve were represented by small percentages.

Even in different parts of the same twenty-foot aquarium the average number of tentacles varied,

although the conditions were, apparently, exactly the same.

As has been noted before, the number of tentacles generally increases with the size and the age of the *Hydra*, though, under unfavorable conditions, the number may decrease with age.

As has been stated by former workers, the number of tentacles regenerated by a decapitated individual is nearly always less than the original number possessed by the *Hydra*. The average number of regenerated tentacles for seven-tentacled *Hydras* was 5.73, for eight-tentacled *Hydras* it was 6.47.

Parke states that the number of tentacles on buds varies from four to six, and is always less than the number possessed by the parent. In the *Hydras* here studied the buds had from six to nine tentacles, and in only 50 per cent. of these cases were there less tentacles upon the bud than upon the parent. In 37.5 per cent. of the budding *Hydras* examined the number of tentacles of bud and parent was the same, and in the remaining 12.5 per cent. of cases the bud had actually more tentacles than the parent.

A Report on the First Forty-three Generations of an Experiment concerning the Effects of Disuse: F. E. LUTZ.

The fly, *Drosophila ampelophila*, was bred for more than forty-three generations under conditions which prevented the use of the wings. There was no indication of any degeneration either in the absolute or relative size of the wing or in the venation.

Darwin's Case of Reversion in Poultry: C. B.

DAVENPORT, Cold Spring Harbor, N. Y.

The cross between a black Spanish cock and white Silkie hen (an albino) produces black chicks, of which the cocks gain some red in the plumage of those feathers that are red in the jungle fowl. Darwin called this reversion. The second hybrid generation reveals the full story. Typically game-colored males and females appear in this generation. The whole matter is explained on the theory that the Spanish contains the factors: color factor, C; jungle fowl color pattern, J; and extra black coat, N; whereas C and N are absent in the Silkie. In the second hybrid generation theory calls for nine blacks to four whites and three games and this proportion is actually obtained.

A Substitute for the Theory of Warning Coloration: JACOB REIGHARD, University of Michigan.

Many of the coral-reef fishes of the Tortugas region are very conspicuous in their natural en-

vironment, as shown by photographs taken by a submerged camera.

The conspicuousness is of the sort typical of warningly colored insects and is often associated with formidable means of defense.

The conspicuousness is not due to secondary sexual coloration.

These fishes do not show aggressive resemblance and such resemblance is unnecessary for them, since their food consists chiefly of fixed invertebrates.

They do not show protective resemblance and have no need of it, since the coral-reef habitat affords them ample protection from their enemies.

Their conspicuousness is not an instance of warning coloration, since they are readily eaten by the commonest piscivorous fish of the region (*Lutianus griseus*), when removed from the reefs, although this fish possesses color vision, forms associations readily and retains these associations for a considerable time, and has therefore the qualities which would enable it to take advantage of warning coloration in its food.

The conspicuousness of the coral-reef fishes has therefore not arisen through selection of any sort, but is an expression of the action of internal forces (race tendency), in the absence of counter-acting selection.

The disagreeable qualities of warningly colored insects is universally held to have been present before these insects became conspicuous. They therefore served at the start to inhibit the attacks of vertebrate foes and thus rendered protective coloration unnecessary for such insects.

The nature of their food has rendered aggressive coloration unnecessary to warningly colored insects.

The conspicuous colors of warningly colored insects have therefore arisen in the absence of selection, under immunity from selection. They are to be attributed to the action of internal forces unchecked by selection.

Other conditions than inedibility may so limit the attacks of vertebrate foes on insects (and other animals) as to render them free from selection from this source and wherever, in such cases, the nature of the food renders aggressive coloration unnecessary the insects are immune from the action of selection and free to develop conspicuousness. Inaccessibility may thus condition conspicuousness, and probably does so in the case of many edible butterflies.

The theory of immunity coloration is proposed as a substitute for the theory of warning coloration,

while at the same time it covers certain cases not covered by the theory of warning coloration. Immunity coloration is defined as follows: "Coloration, not sexually dimorphic, which renders an organism in its natural environment conspicuous to vertebrates; which has no selective value, since it does not aid the organism in escaping vertebrate enemies by concealment (protective coloration), nor in approaching its accustomed invertebrate prey (aggressive coloration), and when associated with disagreeable qualities is unnecessary as a warning to vertebrate foes of the existence of such qualities (warning coloration); it is conceived to have arisen through internal forces under immunity of the organism from selection acting on its color characters." The exclusion of sexually dimorphic characters from the definition is provisional.

The Partulae of the Society Islands, and the Problems of Distribution and Isolation: H. E. CHAMPTON, Columbia University.

The survey of the islands of the Society Group of Polynesia was completed during the years 1907 and 1908, and the results have made it possible to offer relatively final statements regarding the variation and distribution of the species of *Partula* that occur in the group. Each island possesses characteristic forms, that with two exceptions are absent from other islands. The two peaks of Tahiti contain nearly similar forms; the two separated halves of Huahine have the same species, although these exhibit more differences than the species of Greater and Lesser Tahiti; Tahaa and Raiatea are wider apart, although they have the same encircling reef, and their species are far more differentiated; finally, Borabora and Moorea possess unique forms, in correspondence with their total isolation from other islands.

A comparison of the valley faunas in any and all islands reveals a similar relation between geographical separation and racial divergence, and all the islands agree in demonstrating this correspondence. Evidence was presented showing that environmental influences can not be regarded as the immediate factors for racial differentiation, and that mutation has played a large if not an exclusive part in the process. The rôle of natural selection is restricted to a purely negative part.

Some Methods and Results of Pigeon Breeding at the Rhode Island Experiment Station: L. J. COLE, Yale University.

Preliminary Statistics on the Nidification and the Proportions of the Sexes in Pigeons: L. J. COLE, Yale University.

The Inheritance of Egg-producing Ability (Fecundity) in the Domestic Fowl: RAYMOND PEARL and FRANK M. SURFACE, Maine Agricultural Experiment Station.

The data discussed in this paper were obtained from two lines of work. The first of these was an experiment in which for a period of nine years hens have been selected for high egg production. No hens were used as breeders whose production in the pullet year had not been 150 or more eggs. The cockerels used were, after the first year of the experiment, invariably the sons of mothers producing 200 or more eggs in their pullet year.

The second source of data was an experiment in which the inheritance of egg production from mother to daughter was directly measured. Records of the pullet year egg production of 250 daughters of hens laying 200 or more eggs in their (the mothers') pullet year were obtained.

Certain of the most important results obtained may be summarily stated as follows:

1. Selection for high egg production carried on for nine consecutive years did not lead to any increase in the average production of the flocks.

2. There was no decrease in variability in egg production as a result of this selection.

3. The present data give no evidence that there is a sensible correlation between mother and daughter in respect to egg production, or that egg-producing ability (fecundity) is sensibly inherited.

4. In this experiment the daughters of "200-egg" hens did not exhibit, when kept under the same environmental conditions, such a high average egg production as did pullets of the same age which were the daughters of birds whose production was less than 200 eggs per year.

5. The daughters of "200-egg" hens were not less variable in respect to egg production than were similar birds whose mothers were not so closely selected.

*Color Changes of *Oxyopoda arenaria*:* R. P. COWLES, Johns Hopkins University.

Under certain conditions a dark color pattern can be distinctly seen through the carapace of *Oxyopoda arenaria*; under other conditions this pattern disappears.

Many experiments were performed to test the effect of intensity of light, degree of temperature, mechanical and chemical stimuli. It was found that the first two factors determined the appearance and the disappearance of the color pattern.

In direct and diffuse sunlight when the temperature is kept low the pattern is visible, but when the temperature is high the pattern disappears.

In the absence of light at low medium and high temperature the pattern fails to appear.

Of the two factors, intensity of light and degree of temperature, the former is the more important.

A Gynandromorphous Crayfish: E. A. ANDREWS, Johns Hopkins University.

A specimen of *Cambarus affinis* proves upon study to be an immature male with a few external sex organs that should appear only upon the female.

This gynandromorph, or individual with a mixture of organs normally found upon two individuals, male and female, has a normal testis with no sign of ovogenesis, and two normal, but little developed deferent ducts and the two normal male papillae at the bases of the fifth thoracic legs. Moreover, the limbs of the first and the second abdominal somites are as in a normal young male and the hooks of the third thoracic legs are normal.

On the other hand, the third thoracic legs bear two elliptical openings that closely imitate the openings of oviducts. These openings are mere blind cuticular structures and do not communicate with any internal organs.

Most of the gynandromorph crayfishes hitherto known have been females with some male traits.

This case emphasizes the independence of gonad and external sex organ, and is in opposition to internal secretions as a cause of appearance of external sex organs.

Whether such mixtures of sex organs can be due to abnormal fertilizations, to polyspermy, may be decided by future experiments in cross breeding of crayfish. At present the evidence seems to indicate that these gynandromorphs may arise in the ovarian egg.

Organs of Sperm-transfer in Male Crayfish: E. A. ANDREWS, Johns Hopkins University.

Though the sperms of crayfishes appear to be killed by fresh water yet they are transferred by the male to the outside of the female while under water. A comparative study of the reflexes and instincts involved shows the use of three sets of organs in the male that are necessary for the perpetuation of the species. These are the papillae of the last thoracic limbs and the specialization of the first and the second limbs of the abdomen. In *Cambarus* there are also one or two pairs of hooks upon the thoracic legs.

The anatomy of these structures shows that in *Cambarus* the first abdominal appendage is much more complex and accurately adjusted than had been thought, so that these crayfish are even more highly evolved than they had been considered to be. On the other hand, the like appendage of the crayfish of Japan is not fundamentally as much like that of *Cambarus* as had been thought, but more primitive. This tends to lessen the difficulties of one problem of geographical distribution of crayfish by lessening the resemblance of eastern Asiatic to eastern American forms.

The evolution of the accurately interadjusted male and female organs of sperm-transfer in crayfishes seems to admit of no present scientific explanation.

Pelagic Nemerteans: W. R. COE, Yale University.

Comparative anatomical studies of numerous species from various parts of the world leave little doubt as to the affinities of these aberrant forms. Recent discoveries of pelagic species show that they are distributed around the whole circumference of the globe, and although they do not appear to be abundant in any locality, the Arctic and Antarctic oceans are the only large bodies of water without known representatives. The structure of the proboscis, the arrangement of the muscular layers of the body, and the disposition of the blood vessels, indicate their origin from more than a single one of the more generalized types of Hoplonemerteans.

The Breeding Habits of the Squid: GILMAN A. DREW, University of Maine.

It has long been known that female squid with nearly mature eggs have packages of sperm attached to their outer buccal membrane. This summer Professor E. G. Conklin observed a few packages of sperm on the oviduct of a squid. Observations following this have shown that this is not an uncommon, but, on the other hand, not a universal condition.

The transfer of the sperm to both of these loca-

tions has been observed many times during the past summer.

When the sperm is deposited on the oviduct, the male grasps the female around the body just behind the mantle opening, or frequently attaches further back and crawls forward. The dorsal side of the male is usually just below or a little to the left of the ventral side of the female. The male then extends its penis well into its funnel, ejects a bunch of spermatophores, which it catches at the outer opening of the funnel with the end of its left ventral arm. This arm, with the spermatophores, is immediately inserted far into the mantle chamber of the female by the left side of her neck above the funnel, and held there perhaps ten seconds. Its position can sometimes be seen through the transparent mantle of the female. It is then withdrawn, the male releases the female, and a few seconds later the empty cases of the spermatophores escape from the female with the water leaving her funnel. Examination of such a female reveals fresh sperm sacs attached to the oviduct.

The transfer of sperm to the buccal membrane is accomplished while the animals are attached head to head.

The discharge of the spermatophores is similar to *Rossia* as described by Racovitza.

Several females were observed while depositing their eggs. Usually the female rests quietly upon the bottom for several minutes before a string of eggs is to be deposited. In this position she frequently remains until the end of the string protrudes about three quarters of an inch from the funnel. She then begins to swim backward, largely by means of the fin, but partly by water that escapes from the funnel around the egg string. While swimming in this manner, she passes her two dorsal arms between the others and catches the end of the egg string with them and draws it up between the arms as it leaves the funnel. Here it remains for two or three minutes, entirely surrounded by the arms, which are kept nervously moving against each other, while she slowly swims about. Just before sticking the egg string to the bottom, she becomes exceedingly nervous in her actions and frequently goes dancing over the bottom on the tips of her arms with the body perpendicular, in a most sensational manner. Suddenly, while the body is perpendicular, or nearly so, she attaches to the bottom with the ends of her arms, draws down tight against the bottom and then withdraws, leaving the egg string attached.

Molluscan Studies on Lake Champlain: H. F. PERKINS, University of Vermont.

Some Holothurian Structures: CHARLES LINCOLN EDWARDS, Trinity College.

In *Cucumaria frondosa* I have found vestigial anal teeth, well marked in specimens 1-2 mm. long, one developing at the posterior termination of each mid radial line just beyond the bases of the last pair of pedicels and outside of the anus. These anal teeth remain small and can be found in a majority of the adult specimens, but are never functional and hence may be regarded as vestigial. In very young *Holothuria floridana* I have found three fan-shaped calcareous plates, two lateral and one posterior, which function somewhat as anal teeth, disappearing in the adult, and they also are vestigial structures.

In *Cucumaria frondosa*, the female has a simple, conical genital papilla, while in the male it is subdivided into three to ten parts. The distal portion of each part bifurcates, a genital pore terminating each branch, while the proximal portions of all parts fuse in the common base. Heretofore subdivided, or multiple, genital papillae have been known only in a few Elaspoda, but I have seen no record of differentiation in the form of male and female genital papillae. In one *Thyone* and two *Cucumaria* a genital papilla in the male only has been reported.

The Growth of Parts in the Dogfish: WM. E. KELLICOTT, Woman's College of Baltimore.

The weights of the brain, heart, rectal gland, pancreas, spleen, liver and gonads were determined in a series of 315 dogfish (*Mustelus canis*), including specimens from birth, weighing about 76 grams, up to a maximum observed weight of 8,434 grams.

It was found that these organs did not grow at the same rates nor at the rate of the organism as a whole. These parts, except the gonads, are heaviest, relative to the total weight, at birth or soon thereafter and from this time onward constantly diminish in relative weight.

Since the parts of the organism do not grow similarly, description of its growth by recording total weights does not describe the actual growth processes of the whole organism, but chiefly of some predominating parts—in most vertebrates these are the muscles and connective tissues which make up roughly 75 per cent. of the total weight.

In this indeterminately growing form all the parts mentioned tend to be outgrown by the muscles and supporting tissues; a condition of determinate growth might be derived from this

by the action of some mechanism for stopping the growth of these tissues at such a point that the brain and viscera remain competent as physiological elements.

The Criteria of Homology in the Peripheral Nervous System: C. JUDSON HERRICK, University of Chicago.

The synonymy of the peripheral nerves of lower vertebrates is in great confusion. This is largely due to the fact that the exact composition of the various rami (particularly of the cerebral nerves) was formerly imperfectly known, and hence nerves of very diverse composition were often compared on the strength merely of topographic similarities of distribution. With the extension of our knowledge of the nerve components of representative vertebrates, it becomes desirable that a standard method of procedure be established in the determination of homologies and in the selection of names for mixed rami and in other cases in which diversity of usage has arisen. A few rules governing homologies are suggested in the present paper, which will be published in the *Journal of Comparative Neurology and Psychology*.

On a New Species of Goblin Shark (Scapanorhynchus jordani) from Japan: L. HUSSAKOF, American Museum of Natural History.

Scapanorhynchus (Mitsukurina) is a rare shark occasionally taken in the deeper waters of Japan. Only one species has hitherto been known, *S. owstoni* Jordan. In the present paper a second species was described, for which the name *S. jordani* was proposed. It differs from *owstoni* in the much lesser protrusibility of the jaw, much smaller spiracle, smaller gill area and the more forward position of the nostril, eye and spiracle.

The proper generic name of this shark was discussed. The fish was originally described by Jordan under the name *Mitsukurina*; but this genus, as has been pointed out by several investigators, is apparently identical with the Cretaceous form *Scapanorhynchus*. The latter name has priority.

YALE UNIVERSITY

SOCIETIES AND ACADEMIES

THE BIOLOGICAL SOCIETY OF WASHINGTON

THE 453d meeting was held January 23, 1909, with President Palmer in the chair. Several informal notes were presented. Mr. F. E. Matthes offered some notes on snow and winter insects collected in the vicinity of Washington. Among the true snow insects especial interest attaches to *Boreus nivalis* (Neuroptera). This insect is common in the northern states, but has hitherto been considered rare in the District of Columbia. On Christmas day, 1908, and at various times in January, 1909, it was found in abundance in Rock Creek Park. On the date first mentioned, two of this species were observed mating on the snow. On the same day large numbers of winter insects belonging to the Hymenoptera were gathered in the same locality. They represent the winter generation of two Cynipid gall flies, consisting of hermaphroditic individuals, whose larval stages are passed in the roots of oak trees. They oviposit in the young buds of the same tree, thus producing the galls on the leaves in which the summer generation develops. It appears essential, according to observations by Dr. E. A. Schwarz and others, that the ovipositing be done as soon as the buds show the first signs of life in spring. It takes place therefore about the end of February as a rule. In view of this, it seems surprising that the insects should have been found at so early a date as December 25, almost two months prior to the first budding of the leaves.

The difficulties attached to any studies whereby the winter generations of these species might be connected with the corresponding summer generations have thus far proved almost insuperable, and as a consequence no definite correlation exists as yet. For the present the individuals of the winter generation (which look quite unlike the summer generation) are referred to the genus

Andricus. Both *Andricus* species found have atrophied wings, those of the larger species being apparently perfect but about half the size necessary for flight. They thus possess a characteristic also found in *Boreus*. In the male of the latter, however, the wing remnants are of an imperfect and strangely aberrant type.

Mr. M. B. Waite exhibited a Jonathan apple having a peculiar decay. The specimen represented a lot which had been shipped from Colorado to Los Angeles, California, kept there in cold-storage, and then sent to Washington for diagnosis. Three species of apple rot fungi found in the decayed spots were considered secondary since most of the decayed areas were free from fungi or bacteria. The discolored areas, often in the form of a band around the apple, were firm in texture, light brown in color, and extended to a moderate depth in the flesh of the apple. The cells in the discolored areas were collapsed and ruptured, thus coinciding with frost injury. The damaged area was concluded to be due to freezing, or, since the apple stands freezing, to the peculiar conditions of thawing out after freezing.

Dr. H. M. Smith announced and commented upon the transfer of the administration and personnel of the federal fur-seal service to the Bureau of Fisheries.

Dr. B. W. Evermann reported an observation made by his brother, A. M. Evermann, near Burlington, Indiana, showing that fox squirrels sometimes feed upon the seeds of the cocklebur (*Xanthium strumarium*). The observation was made January 19 when snow covered the ground. The squirrels carried the burr to a log at the edge of a field and there got at the kernels by gnawing away one side.

He also reported the capture of a barn owl in Carroll County, Indiana, in December, 1908. This species had not been previously recorded from that county.

The regular program consisted of the following four papers:

Bee Diseases: E. F. PHILLIPS.

The honey bee, *Apis mellifera*, is subject to several specific diseases which are well recognized among practical bee keepers. The causes of all of them are not fully understood. Two of these attack the bee in its embryonic stages and are now designated American foul brood and European foul brood. They attack the bee just about the time that pupation begins and the colony is depleted because as the adult bees die from natural causes there are not enough bees emerging

to replace them. The cause of American foul brood has by inoculation experiments been determined to be *Bacillus larvæ*. This organism grows well only on a medium prepared by mashing healthy bee larvæ and sterilizing by filtration. Fifteen minutes of boiling is required to kill the spores of the bacillus. The cause of European foul brood is not known. There are other maladies of the brood and of the adult bee. The methods of treatment and means of spread were discussed.

Federal Control of Fisheries in International Waters: B. W. EVERMANN.

He discussed briefly the questions of federal control of migratory birds, of migrating fishes, of inter-state waters and of international waters. Attention was called to the valuable work which the Hon. George Shiras, III., has done, and is still doing, in calling attention to the power of the government in matters such as these which experience has demonstrated can not be properly handled by the respective states. When a member of Congress Mr. Shiras introduced two or three bills providing for federal control of migratory birds and fishes, and one providing for federal control of inter-state waters.

On April 11, 1908, a convention was entered into between the United States and Great Britain according to the terms of which uniform regulations will be provided governing the fisheries on the United States and Canadian sides of our northern boundary. The special International Fisheries Commission appointed under the treaty is now drawing up its report which must be submitted to the respective governments by June 3.

This report, it is understood, will contain a complete system of regulations for the fisheries in all international waters between the United States and Canada.

A Remarkable Flight of Bats in Luzon: HUGH M. SMITH.

He presented notes on a remarkable flight of small bats observed by him near Montalban, Luzon, P. I., on December 31, 1907. At 5.40 P.M. a solid column of bats began to emerge from a large cave about 1,200 feet above the Mariquina River. The bats flew rapidly in a straight, unbroken, closely-packed line for fifteen minutes, and disappeared over a mountain range in the direction of Manila without a single bat having left the column. American engineers at the place reported that this flight had occurred at practically the same time each day during the two years they had been there; and from other sources it

was learned that the same thing had been observed for at least thirty years.

A Visit to the Bat Cave in Luzon: PAUL BARTSCH.

He described the cave from which came the flight of bats referred to by the preceding speaker. The cave is a large one. Its main entrance is about 35 feet high and 25 feet wide, and difficult of access. A short passage connects the entrance with the central dome which has a diameter of about 150 feet and height of about 200 feet and perforates the mountain top. From this chamber passages open in various directions, frequently expanding into large rooms, some of which have wonderful stalagmites and stalactites, while others are simply glazed with a glistening lime deposit. An hour and a half was spent going from chamber to chamber and the native guide stated that he might continue for half a day without retracing his steps. Bats of several species were seen flitting about or clinging to the wall of the cave everywhere, but not enough to make a hundredth part of the swarm seen on the night of the last of December, 1907. Owing to the failure of the bat flight the previous night (July 4, 1908) the party had expected to find dead bats in the cave, believing that some epidemic might have killed them. This seemed the probable solution since on their previous visit the party had been assured that the bats had never been known to fail to make their appearance at a certain hour for many years. Careful search of the floor which was richly covered with guano, failed to reveal any dead individuals, and the whereabouts of the immense flight remains a mystery at present.

M. C. MARSH,

Recording Secretary

THE CHEMICAL SOCIETY OF WASHINGTON

THE 188th meeting of the Washington Chemical Society was held at the Cosmos Club on Thursday, February 11, 1909, at 8 P.M. President Walker presided, the attendance being 62. Eleven new members were added to the roll and two resignations were announced. J. M. Bell, of the Bureau of Soils, was appointed chairman of the committee on communications and M. X. Sullivan, of the Bureau of Soils, chairman of the entertainment committee. Arrangements were announced to hold the annual smoker at the Riggs House on Thursday, February 18. The following papers were presented:

"The Formation of Gluconic Acid by the Olive Tubercle Organism and its Physiological Function," by C. L. Alaberg.

"The Chemical Constituents of Oil of Erigeron and Wild Sage," by Frank Rabak.

"China Wood Oil," by E. W. Boughton.

J. A. LE CLERC,
Secretary

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

At the 428th regular meeting of the Society, held at the Cosmos Club February 2, 1909, the following program was presented:

A Newly Discovered Siouan Dialect: DR. JOHN R. SWANTON.

Dr. Swanton visited the small remnant of Tunica Indians living close to Marksville, La., in November, 1908, for the purpose of correcting and amplifying the linguistic material recorded by Dr. Gatschet over twenty years ago. In the course of his investigations he had the good fortune to find a single survivor of an Indian tribe formerly living on the Yazoo River and known from French accounts as Ofogoula. A sufficient vocabulary was obtained to show that the language spoken by them was not Muskogean, as had hitherto been supposed, but a Siouan dialect related to those of the Biloxi and the eastern Siouan tribes. It is peculiar in substituting *f* for *s* in many situations and *te* for *y* in others. The proper name of the tribe is Ofo, and probably has nothing to do with Choctaw ofe, "dog," as has hitherto been supposed.

Exhibition of Ethnographic Specimens by Members of the Society.

Dr. I. M. Casanowicz exhibited a silver lamp with eight burners used by the Jews in the Hanuga ceremony, the origin of which was explained at some length. This lamp is the property of Ephraim Benguiat, of New York. Dr. Casanowicz also showed a design representing a globe made of the book of Ecclesiastes in Hebrew characters in a single line.

Mr. Edwin P. Upham, of the Smithsonian Institution, exhibited and gave the place of origin of a series of stone scrapers and a series of stone axes. A general examination and discussion followed on the part of the members of the society.

JOHN R. SWANTON,
Secretary

THE BIOLOGICAL AND GEOLOGICAL SECTION OF THE ACADEMY OF SCIENCE AND ART OF PITTSBURG

At a regular meeting of the section on February 2, Mr. F. G. Clapp spoke on the "Influence

of Geological Structure on the Occurrence of Oil and Gas." Mr. Clapp briefly discussed the "anticlinal theory" of White and Orton and indicated the other factors which must always be considered in connection with it in order to make determinations of practical value. The following generalizations were made in regard to the fields of southwestern Pennsylvania and northern West Virginia:

1. All conditions being favorable, the accumulations of oil and gas do show a definite relation to the geologic structure.

2. With but few exceptions the greatest elongation of the pools is approximately parallel to the axes of the folds.

3. When both oil and gas are present in a stratum of sandstone, they are distributed according to their densities, the oil in the lower and the gas in the higher portion of the layer.

4. When oil and salt water are present the oil generally occurs in the part of the stratum lying directly above the water level.

5. When salt water is absent the oil may occur at the bottom of the syncline, or may be part way up the anticlinal slope.

6. Oil may occur on a "structural bench," where the dip of a stratum changes from gentle to steep.

7. Gas occurs mainly near the crests of anticlinal folds.

8. It occurs, however, in greatest volume in certain portions of the anticlinal crests which take the form of structural "domes."

9. Gas occurs in volume also at many widely scattered points, due to local changes in the dip and texture of the rocks.

The unconformity at the base of the Pottsville formation was briefly described, and the statement made that in certain fields it has a decided influence on the relation existing between the position of the oil and gas deposits and the geological structure as determined by the surface rocks. In general the interval between the surface rocks and the deeper oil and gas "sands" diminishes toward the north and west, and this change frequently shifts the axes of the anticlines and synclines in the deeper sands a fraction of a mile from the position of the same axes in the surface formations. Other changes in the intervals between the various sands must be taken into account in locating oil or gas deposits.

THE FIRST PAN-AMERICAN SCIENTIFIC CONGRESS, HELD IN SANTIAGO, CHILE, DECEMBER 25, 1908-JANUARY 6, 1909

THE first Latin-American Scientific Congress, which was convened in Buenos Aires in 1898, was projected by the Scientific Society of that city, and successfully carried out. It was attended by representatives of twelve Latin-American republics, and yielded results of such importance that a second congress was convened at Montevideo in 1901; and this was followed by a third at Rio Janeiro in 1905. Arrangements were made for a fourth meeting at Santiago, Chile, in 1908, and the Chilean organization committee,¹ feeling that the activities of the congress, which had been limited to the discussion of Latin-American problems and interests chiefly, should be extended to a fully Pan-American scope, decided that the Santiago meeting should be known as "The First Pan-American Scientific Congress."

The organization committee, through the medium of the Chilean government, extended to the government of the United States an invitation to participate. Secretary Root brought the matter to the attention of President Roosevelt,² and the

¹ The organization committee was constituted as follows: *Honorary President*, Marcial Martinez; *President*, Valentin Letelier; *Vice-president*, Manuel E. Ballesteros; *General Secretary*, Eduardo Poirier; *Assistant Secretary*, Augusto Vicuna S.; *Treasurer*, Octavio Maira; *Alejandro Alvarez*, Jose Ramon Gutierrez, Salvador Izquierdo S., Alejandro del Rio, Miguel Varas, Luis Espejo Varas, Anselmo Hevia Riquelme, Vicente Izquierdo, Domingo V. Santa Maria.

² *The President:* The government of Chile has invited the government of the United States to

MSS. intended for publication and books, etc., intended for review should be sent to the Editor of SCIENCE, Garrison-on-Hudson, N. Y.

President transmitted the invitation to Congress, accompanied by a commendation to join in and to be represented by delegates at the Pan-American Scientific Congress, which is to assemble under its auspices at the capital city of Santiago during the ten days beginning December 25, 1908. The work of the congress will comprehend nine sections, devoted, respectively, to pure and applied mathematics, physical sciences, natural sciences, engineering, medicine and hygiene, anthropology, jurisprudence and sociology, pedagogy, and agriculture and animal industry.

Latin-American scientific congresses were held in 1898 at Buenos Aires, in 1901 at Montevideo and in 1905 at Rio de Janeiro. Growing out of these previous conferences the congress of 1908 will be for the first time Pan-American. It will study and discuss many great subjects in which all the American republics have in common special interests; and its aim is to bring together the best scientific thought of this hemisphere for the scrutiny of many distinctively American problems and for an interchange of experience and of views which should be of great value to all the nations concerned.

It is therefore eminently appropriate that the United States should be adequately represented at this important First Pan-American Scientific Congress and should embrace this opportunity for cooperation in scientific research with the representatives of the other American republics. It is worthy of consideration that, in addition to the purely scientific interests to be subserved by such a congress and in addition to the advantages arising from an interchange of thought and the intercourse of the scientific men of the American countries and the good understanding and friendly relations which will be promoted, there are many specific relations arising from the very close intercourse between the United States and many Latin-American countries, incident to our expanding trade, our extending investments, and the construction of the Panama Canal, which make a common understanding and free exchange of opinion upon scientific subjects of great practical importance.

To make our representation possible I have the honor to recommend that the Congress be asked to appropriate the sum of \$35,000, or so much thereof as may be necessary, to enable the United States to send a number of delegates corresponding to the number of sections into which the congress is to be divided, together with a secretary

tory message.* In due course the invitation was officially accepted, and a liberal sum appropriated for the purposes of the congress. The committee of organization also extended invitations, through the Department of State at Washington, to a number of universities and other institutions and societies. As a result a large delegation was accredited to the congress. The membership of the delegation and the institutions represented are as follows:

Government Delegates

L. S. Rowe, University of Pennsylvania.
Paul S. Reinsch, University of Wisconsin.
Hiram Bingham, Yale University.
A. C. Coolidge, Harvard University.

and disbursing officer, and to pay other necessary expenses.

Inasmuch as it is desired that all communications or scientific works to be presented to the congress be received before September 30, it is much to be hoped that provision for the participation of this government may be made at an early date and that the appropriation be made immediately available.

Respectfully submitted,

ELIHU ROOT

Department of State,

Washington, December 19, 1907.

To the Senate and House of Representatives:

I transmit herewith for the consideration of the respective Houses of the Congress a report of the Secretary of State representing the appropriateness of early action in order that in response to the invitation of the government of Chile the government of the United States may be enabled fittingly to be represented at the First Pan-American Scientific Congress, to be held at Santiago, Chile, the first ten days of December, 1908.

The recommendations of this report have my hearty approval, and I hope that the Congress will see fit to make timely provision to enable the government to respond appropriately to the invitation of the government of Chile in the sending of delegates to a congress which can not fail to be of great interest and importance to the governments and peoples of all the American republics.

THEODORE ROOSEVELT

The White House,

December 21, 1907

 Paul S. Reinsch, University of Wisconsin.
 Hiram Bingham, Yale University.

Scientific Societies

L. S. Rowe, American Academy of Political and Social Science.
 L. J. Doran, National Educational Association.

In June, 1908, meetings of the government delegates were held at the State Department, Washington, under the tutelage of Secretary Root, who conveyed to them such instructions as were deemed necessary. Arrangements were made for the preparation and translation of papers dealing with appropriate subjects for presentation at the congress, and for the disposal of the sum allotted by the Department for the purposes of the congress. The organization of the delegation was completed by the selection of Dr. L. S. Rowe as chairman and Professor Paul S. Reinsch as vice-chairman.

Under the guidance of Dr. Rowe a number of the delegates assembled in Buenos Ayres early in December, where they were the recipients of the hospitality of the president of the republic and the members of his cabinet, and of the ministers of the

United States and Chile. Visits were made to numerous institutions of learning, hospitals, municipal buildings, parks, etc., and the visit to the University of La Plata was signalized by an exceptionally cordial interchange of courtesies. On December 10 the party crossed the Andes and established headquarters in the Hotel Oddo in Santiago. Here, before and during the sittings of the congress, the delegation held frequent meetings to plan and discuss their work in the congress. Meantime other delegations, representing seven North American and Central American and nine South American republics, were on hand; and the meeting for the selection of officers for the congress was held at the University of Chile on December 24.⁴

At 10 P.M. on Christmas Day the opening session was held in the spacious Municipal Theater, and proved a most impressive ceremony. The president of the republic, Señor Pedro Montt, was present, and addresses were made by various officials of the congress and by chairmen of the various national delegations. The address of Dr. Rowe, chairman of the American delegation, delivered in Spanish, was enthusiastically received.⁵

⁴The result was as follows: *President*, Enrique R. Lisboa, Envoy Extraordinary and Minister Plenipotentiary of Brazil; *Vice-presidents*, Lorenzo Anadon, Envoy Extraordinary and Minister Plenipotentiary of Argentina; Fredrico Susviela Guarch, Delegate of Uruguay, and Matias Manzanilla, Delegate of Peru; *Secretaries*, Emilio Fernandez, Delegate of Bolivia; Melchor Lasso de la Vega, Delegate of Panama, and Enrique Martinez Sobral, Delegate of Mexico.

⁵ ADDRESS OF DR. L. S. ROWE AT THE OPENING SESSION

Your Excellency, Ladies and Gentlemen:

This congress possesses an historical significance which it is difficult for us to appreciate at the present time. It marks an epoch in the intellectual development of the American continent.

Complete isolation from one another has characterized the situation of the countries of this

The committee of organization was prompt in the preparation of the program continent. This isolation has been one of the greatest obstacles to progress. The failure to develop a spirit of intellectual cooperation has resulted in a great loss of energy and has been one of the most important obstacles to the solution of many problems which would long ago have been solved had we been able to unite our energies and profit by each other's experience. The true scientific spirit has a far deeper significance than the mere desire to conduct investigations. It can not reach its highest expression if there exist petty rivalries or jealousies. For this reason the development of the scientific spirit contributes so much to the growth of a true international fraternal spirit. A vigorous spirit of cooperation, developed amongst the scientists of the American continent, will enable us to destroy the last traces of the epoch in which the words "stranger" and "enemy" were synonymous.

The industrial development of the last century offers lessons of much importance to the scientific world. A study of the economic growth of modern countries clearly shows that the principle of competition is gradually giving way to the principle of cooperation.

The formation of trusts as well as the growth of trades' unions constitutes the concrete expression of these new tendencies. The eighteenth century and a considerable portion of the nineteenth were dominated by a spirit of individualism. During more than four generations, it was taken for granted that human progress is dependent on the struggle for existence and the conflict between individual and individual. During the nineteenth century the application of biological principles to human society strengthened this idea. It is the mission of the twentieth century to demonstrate that we must regard the principle of cooperation rather than that of competition as the fundamental principle of social progress.

In this congress it is our high privilege to inaugurate a new epoch giving concrete form to the idea of intellectual cooperation. In the International Bureau of American Republics we have a central organization admirably adapted to contribute toward the realization of this idea. We need such a center in order to place investigators in different portions of the American continent in contact with one another, and in order that the results of such investigations may be made the common property of all the nations of America.

of meetings, and the press of the city was most generous and helpful in its treatment of the congress. The sectional meetings, which continued during eight days, were held separately under the following heads:

1. Mathematics, Pure and Applied.
2. Physical and Chemical Sciences.
3. Natural Sciences—Biology, Paleontology, Geology, Anthropology, etc.
4. Engineering.
5. Medicine and Hygiene.
6. Jurisprudence.
7. Social Sciences.
8. Pedagogic Sciences.
9. Agriculture and Zootechny.

The program was followed, with necessary modifications from day to day. The majority of the papers were read in full or in extended abstracts, and discussion was free and often spirited. Naturally, popular interest centered largely about the sections dealing with practical problems, as education, sanitation, social science and engineering; but the more abstract sciences were not neglected. Owing to the great range of the work of the congress and the multiplicity of papers presented in the various sections, no attempt can be made in this place to present the work and results in detail. The list of papers presented by members of the American delegation and forwarded by the other

In the name of the delegation of the United States of America, I desire to express our sincere thanks for this opportunity to take part in the deliberations of this congress. No better opportunity could have been offered to become acquainted with our colleagues and fellow investigators. The ties here formed possess a significance far deeper than the personal satisfaction they imply. This visit can not help but enlarge our mental horizon, broaden our scientific activity, and strengthen the influence of our university instruction. We congratulate ourselves on the privilege of being present, and desire also to express our appreciation of the great service performed by this republic in giving such vigorous impulse to the spirit of scientific solidarity.

contributors for the United States is as follows:*

Astronomical Problems of the Southern Hemisphere: H. D. CURTIS.

The Electronic Theory of Matter: W. B. SMITH.

Recent Progress in Spectroscopy: A. A. MICHELSON.

Statistics of the Use of Nitrate of Soda in the United States: CHARLES E. MUNROE.

The Economy of Fuels: WILLIAM KENT.

Future Supply of Iron Ore: HENRY M. HOWE.

The concluding session of the Congress was held at the university in the forenoon of January 5, and various matters of gen-

*This list is in part a translation from the Spanish, and may be somewhat imperfect.

eral interest were disposed of. These included a discussion of methods of procedure, policy and scope of future congresses, relation of the congress to government and science, etc. A number of resolutions, passed by the sections or presented by the delegations, were offered and adopted.*

* Resolution, extending to the governing board and director of the International Bureau of American Republics the thanks of the Pan-American Scientific Congress for the offer of cooperation:

WHEREAS: The Pan-American Scientific Congress has received with much satisfaction the cordial message of greetings from the Bureau of American Republics, and the kind offer of cooperation, be it

Resolved, That the formal thanks of the congress be transmitted to the governing board and director of the bureau, and that it be recommended to the members of the organization committee of the next Scientific Congress to avail themselves in every possible way of the valuable services which the bureau can render.

Resolution, recommending the establishment of a Section of American Bibliography in the International Bureau of the American Republics.

Recognizing the importance of establishing closer relations between investigators throughout the American continent and of disseminating the results of scientific investigations, the Pan-American Scientific Congress

Resolves, To recommend to the governing board of the International Bureau of the American Republics:

1. That a special section be established in the International Bureau of the American Republics to be known as the "Section of American Bibliography."

2. That the director of the bureau invite authors and investigators to send their publications to the bureau, on receipt of which notice thereof will be published in the Bulletin, which notice shall include a brief summary of the contents of such publication and the price thereof.

3. That the bureau secure for investigators any such publications at a price to be indicated in the Bulletin.

4. That the bureau endeavor so far as practicable to secure official publications for investigators.

5. That the bureau keep a record of the published progress of larger schemes of scientific investigations of Pan-American bearing.

By a practically unanimous vote it was decided to hold the next meeting in Washington in October, 1912. This action was cabled to the State Department, and Secretary Root responded in the following message:

Please express to the Pan-American Scientific Congress the satisfaction with which this government receives the announcement that Washington has been selected as the meeting-place of the congress in 1912.

A committee of five members^b was appointed to arrange with the Department of State at Washington for the appointment of a permanent organization committee for the prospective meeting.

A farewell session was held in the Municipal Theater on the afternoon of January 5, at which fitting addresses were made by officials and delegates;^c and at

^b L. S. Rowe, George H. Rommel, W. H. Holmes, John Barrett, director of the Bureau of American Republics, and Elmer E. Brown, commissioner of education.

^c CLOSING ADDRESS OF DR. L. S. ROWE

Mr. President, Ladies and Gentlemen:

The honor conferred upon my country through the designation of Washington as the next meeting place of this great assembly is the more significant because of its spontaneous character. For this demonstration of confidence, good will and fraternal solidarity I want to thank you, not only in the name of the delegation of the United States of America, but also on behalf of that larger body of scientists and investigators who are imbued with the same spirit that has actuated this congress, and who now look forward to the privilege of welcoming to our shores the men upon whose efforts the progress of this continent depends. We can not hope to surpass the hospitality of this great republic, but we can assure you that the welcome will be no less sincere, and the determination to place every possible facility at your disposal, no less effective than has been the case here in Chile.

Viewed in its proper perspective, this congress has been one of the most extraordinary assemblages of modern times; more extraordinary in many respects than either the Hague or the Pan-American conferences. That a large group of men,

might a dinner was given in the hall of the university, at which there was a generous representation of every section of a great continent, should be able to get together and, casting aside all petty prejudices, freely and frankly exchange the results of their careful investigations and ripe experience, is not only a tribute to the culture of this continent, but is also an indication of the extent to which our ideas have advanced beyond those which we inherited from our European mother countries.

The fact that we have met to place the results of the best scientific thought at the disposal of all the countries here represented, and through them at the service of the civilized world, contains a lesson of deep and lasting import which no other assembly of modern times has been able so clearly to impress upon the civilized world.

The historian of the intellectual development of the American continent, in reviewing the work of these assemblies, will probably give to the Santiago congress the honor of having clearly demonstrated that the republics of the American continent, because of their geographical position; because of the peculiar conditions under which they were settled; and because of the special racial problems which they present, are confronted by a series of problems distinctively American. The mere fact of the existence of these problems involves an obligation not only to ourselves, but to the civilized world to concentrate our efforts upon their solution. Through their solution we can make that contribution to the progress of mankind which the world has the right to expect of us.

We can best hope to do this by carrying to our respective countries the spirit that has hovered over this congress—that of service in its broadest and highest sense. This spirit of service must be made the key-note of our national and of our international relations. The republics of the American continent must demonstrate to the civilized world that the willingness and determination to be of service to our fellow-men is the cornerstone of a philosophy which the nations of this continent are determined to make the guiding principle of their conduct.

I can see a time, not far distant, when with each conquest of science the question will immediately arise in the mind of every American, "How can these results be made of service to the democracies of this continent?"—a time when in every field of endeavor the American republics may call upon one another for counsel in the solu-

expression of good feeling and a striking display of oratory.

The social features of the congress were most noteworthy. The president of the republic, besides giving the usual official reception, entertained the foreign delegates at dinner, invitations being extended to a limited number each day during the congress. Receptions were given under government auspices at the principal social clubs. The American Minister, the French, Brazilian and Argentine Ministers, and numerous prominent citizens entertained the delegates. Members of the American and other delegations were guests at a number of charming haciendas in the vicinity of Santiago; and the American delegation entertained at dinner members of the organization committee, chairmen of various national delegations and others. Visits were made to institutions of learning, museums, art galleries, hospitals and manufacturing establishments, and no effort was spared by the officials of the congress to make the visit of the foreign delegates enjoyable and profitable. The writer wishes to express his personal appreciation of these courtesies

of their problems, and be certain to receive the best expert advice. Then, and not till then, shall we have developed a real continental spirit; then, and not till then, shall we have fulfilled the obligations which our privileged position in the world's affairs has placed upon us. I can imagine no greater distinction for the next congress than the possibility of marking a further step in the development of this spirit of service and of continental solidarity.

And now, in closing, let me again extend the thanks of the delegation of the United States of America to you, the members of the organizing committee, for your broad grasp of the purposes of the congress and the skill with which these purposes have been made real and effective; to you, our colleagues, for your cordial reception of newcomers in your midst, and finally to the government and people of Chile for the warm-hearted hospitality which we have enjoyed.

sies and attentions, and to say that he approached South America somewhat oppressed by the thought that he should find himself a stranger in a strange land, but that, on the contrary, there was not a day of the two months spent in the Latin-American countries on which he was not made to feel entirely at home and among appreciative and generous friends.

The universal feeling at the close of the congress was that the meeting had fully justified the plans of its projectors; and the story is not entirely told when it is stated that the elaborate program, covering nearly every branch of science, was successfully carried out. The more thoughtful find in this and in kindred assemblages, much that is of significance for the future of the American republics. This congress was a decided step in the direction of bringing about a better understanding among the nations represented. It was a step toward a fuller appreciation of the common interests of each and every American nation. It was an appreciable forward step in the development of the means and methods of promoting the common interests of the continent. It was a step toward making the experience and the accumulated wisdom of each people represented the experience and wisdom of all. In the Section of Pedagogy, the best that has been developed in the theory and practise of teaching was made the common property of all the American republics. In the Section of Sanitary and Medical Science, the latest achievements of each nation in the battle with disease were made familiar to every participant. In the Section of Agriculture and Zootechny, steps were taken in the direction of properly utilizing and conserving the resources of the continent in these important realms. In the Section of Engineering, the best methods of overcoming the various physical obstacles to progress and of winning the riches of the earth, were

explained for the benefit of all America. In the Section of Government and Law, the principles of statecraft and the administration of justice were discussed for the benefit of every American government. In the Section of the Fiscal Sciences, practical methods of conducting the monetary affairs of the nations were presented and explained. And in every other branch of science, practical and abstract, the various forces and agencies that contribute toward progress and enlightenment were in a measure the subject of serious attention. The congress was an initial step toward making the best of all the peoples of the western hemisphere. It was an initial step in making the best, for to-day and for all time, of the resources of the continent. It was an initial step which in many ways must make for the peace and prosperity of the continent. It was a noteworthy step in conformity with manifest destiny as expressed in the phrase "America for Americans."

The success of the congress of 1912 depends upon the interest displayed in it by the scientific world, and on the support accorded by the Pan-American governments. The time is ample, and the appointment of an organization committee representative of a wide range of scientific interests is the first step in making the Washington meeting an event worthy of the nation and its capital.

W. H. HOLMES

BUREAU OF AMERICAN ETHNOLOGY

MARTIN HANS BOYE

Dr. M. H. Boye died at Coopersburg, near Bethlehem, Pa., on March 5, aged ninety-seven years. He was born in Copenhagen, Denmark, in 1812, and in 1832 was graduated from the University of Copenhagen and in 1835 from its Polytechnic School, studying under Oersted, Zeise and Fodchhammer. In 1836 he removed to Philadelphia and entered the University of Pennsylvania, studying chemis-

try under the late Dr. Robert Hare. He was graduated from the university as doctor of medicine, but never practised regularly. In 1838 he was appointed assistant geologist of the first geologic survey of Pennsylvania. In 1845 he was elected professor of natural philosophy and chemistry in the Central High School of Philadelphia and retained this position for fourteen years.

In 1839 he was associated with Robert and James Rodgers, in analyzing limestone, coal, iron ore, etc. While engaged in these analyses he discovered a new compound of platinum chloride with nitric oxide. Because of this discovery he was elected to the American Philosophical Society, and in 1840 helped to organize the American Association of Geologists. He was the only surviving founder of this association and of its successor, the American Association for the Advancement of Science, of which he was a fellow for sixty years. In 1848 he also discovered the first of the violent explosives, perchloric ether, which he proved was ten times as powerful as gunpowder. He also found a safeguard against its unexpected explosion by dilution with alcohol. He was thus an important pioneer in the field of smokeless powder.

Dr. Boyè was the author of many papers on scientific subjects. In 1845 he invented a process of refining oil from cotton. Heretofore the product refined was almost black and very thick. His method produced a bland and colorless oil adapted for cooking or for salad dressing. At the age of eighty-one Dr. Boyè made an extended trip to Alaska, and at the age of eighty-five visited Honolulu and witnessed the transfer of the Hawaiian Island to the United States.

In his will Dr. Boyè devised the sum of \$12,000 to the University of Pennsylvania Hospital.

THE DARWIN CENTENARY

The council of the senate of Cambridge University reports that the committee appointed by the council has informed the council that in July of last year letters signed by the chancellor were sent to more than 300 universities, colleges, academies and other cor-

porate bodies inviting them to appoint delegates to attend the Darwin celebration from June 22 to June 24, 1909. In answer to these invitations more than 200 delegates have been appointed. Since the beginning of the year individual letters of invitation have also been sent by the vice-chancellor to certain distinguished men of science, benefactors of the university and others.

A letter containing an invitation to a banquet on June 23 has been sent to about 150 resident members of the university, including heads of colleges, officers, professors and readers, members of council, university lecturers, demonstrators and other teachers connected with biological departments, fellows of Christ's College, contributors to the volume of essays, "Darwin and Modern Science," to be published by the University Press, and a few others selected on account of their official position or because of their connection with biological science. It is proposed to hold the banquet in the new Examination Hall, and it is estimated that between four and five hundred of those who have been invited will be present.

It is proposed that a letter of invitation to the reception by the chancellor in the Fitzwilliam Museum, on June 22, should be sent by the vice-chancellor to every member of the electoral roll.

A copy of the provisional program has been sent to all delegates. The committee has furnished the council with an approximate estimate of the expense likely to be incurred in carrying out the program. This amounts to considerably more than £500, but it is hoped that it may be possible to provide the excess above that sum by private subscriptions, and the council does not therefore ask the senate to authorize the expenditure of more than £500 from the university chest.

SCIENTIFIC NOTES AND NEWS

The many friends of Major J. W. Powell, both in this country and abroad, will be glad to learn that congress appropriated \$5,000 for the erection of a memorial to him, on the brink of the Grand Canyon of the Colorado which he explored.

DR. J. J. STEVENSON, who has recently retired from the active duties of the chair of geology at New York University, has gone to California. He expects to spend the summer in Europe.

MR. C. L. VAN DINE, Stanford, about 1900, late territorial entomologist of Hawaii, has been appointed special agent of the Department of Agriculture in charge of sugar-cane and rice investigations. Mr. David T. Fullaway, Stanford, 1908, his assistant, is promoted to be territorial entomologist of Hawaii.

PROFESSOR WM. W. PAYNE has resigned the directorship of Goodsell Observatory, Carleton College, and has retired upon the Carnegie Foundation. He retains charge of the observatory time service and is still owner, editor and publisher of *Popular Astronomy*. Dr. H. C. Wilson has been appointed director of the observatory.

MR. R. C. PUNNETT has been appointed superintendent of the museum of zoology, at Cambridge, in succession to Dr. S. F. Harmer, who recently accepted the keepership in zoology at the British Museum of Natural History.

M. DELAFOND will succeed M. Nivoit as director of the Paris School of Mines.

THE University of Edinburgh will, at the approaching spring graduation, confer the honorary degree of LL.D. on Professor Alexander Crum Brown, till lately professor of chemistry in that university.

DR. ADOLF FRANK, the eminent chemist, has celebrated his seventy-fifth birthday.

THE portraits of the following former vice-chancellors have been presented to the University of London, and have been framed and hung in the vice-chancellor's room: Sir John W. Lubbock, Sir John Shaw-Lefevre, Sir Edward Ryan, Sir George Jessel, Sir Julian Goldsmid, Sir John Lubbock (now Lord Avebury), Sir James Paget, Sir Henry Roscoe, Dr. A. Robertson (now bishop of Exeter) and Dr. P. H. Pye-Smith.

THE following fifteen men of science have been nominated by the council of the Royal Society for election to membership: Mr. E. C.

C. Baly, Sir Thomas Barlow, Bart., Rev. E. W. Barnes, Dr. F. A. Bather, Sir Robert Hadfield, Mr. A. D. Hall, Dr. A. Harden, Mr. A. J. Jukes-Browne, Professor J. G. Keck, Professor W. J. Lewis, Professor J. A. McClelland, Professor W. McFadden Orr, Dr. A. B. Rendle, Professor J. Lorrain Smith and Professor J. T. Wilson.

MR. J. G. BARTHOLOMEW, head of the Geographical Institute, the map house of Edinburgh, has been elected an honorary corresponding member of the Société de Géographie de Paris.

THE Smith's Prizes at Cambridge have been adjudged as follows: H. W. Turnbull, B.A., Trinity College, for his essay "The Irreducible Concomitants of Two Quadratics in n Variables"; G. N. Watson, B.A., Trinity College, for his essay "The Solution of the Homogeneous Linear Difference Equation of the Second Order, and its Applications to the Theory of Linear Differential Equations of Fuchsian Type."

DR. FREDERIK VAN EEDEN, of Amsterdam, who twenty years ago established a successful clinic for the mental treatment of disease, is at present in this country.

DR. HUBERT LYMAN CLARK has sailed for Jamaica to make collections on the reefs at Port Antonio.

AT the last meeting of the Middletown Scientific Association Dr. W. G. Cady, associate professor of physics at Wesleyan University, gave a lecture on "Electrical Oscillations."

THE Chicago Chapter of the Sigma Xi Society held its winter meeting on March 9. Professor W. L. Tower presented a paper on "Some Effects of Changed Environment upon Evolution Processes." Nine new members were admitted to the society.

THE Lowndean professor at Cambridge, Sir Robert Ball, F.R.S., lectured on "Ancient and Modern Views of the Constitution of the Milky Way" before the Cambridge Antiquarian Society on March 1.

SIR VICTOR HORSLEY will deliver the Linacre lecture at St. John's College, Cambridge, on

May 6, the subject of the lecture being the "Motor Area of the Brain."

MR. HENRY BAUSCH, second vice-president of the Bausch and Lomb Optical Company, and especially interested in the department of microscopes and scientific apparatus, died on March 2, at the age of fifty years.

DR. HERMANN EBBINGHAUS, professor of philosophy at the University of Halle, founder and editor of the *Zeitschrift für Psychologie*, one of the most eminent German psychologists, has died at fifty-nine years of age.

THE death is also announced of Professor Victor Egger, professor of philosophy and psychology at the Sorbonne, and distinguished chiefly by his work in psychology.

At the meeting of the National Academy of Sciences in April, 1908, as part of the movement for encouragement of cooperative research, a special committee was appointed on paleontological correlation consisting of Messrs. Walcott, Dall, Scott and Osborn. A grant of \$500 was voted from the Bache Fund. As chairman of the section of vertebrate paleontology Professor Osborn has secured the cooperation of a number of foreign and American paleontologists, including Louis Dollo, of Brussels; Eberhard Fraas, of Stuttgart; Charles Depéret, of Lyons; Ernst Koken and F. von Huene, of Tübingen; S. W. Williston, of Chicago, and W. B. Scott, of Princeton. The council of the New York Academy of Sciences has voted to cooperate in this work by the publication of a series of correlation bulletins. The first bulletin now in press contains a report of progress for 1908. The author of the second bulletin is Professor Dollo, who covers the succession of vertebrates in Belgium. The third covers the work of Santiago Roth on the succession of mammalian horizons in Patagonia.

THE U. S. Geological Survey in cooperation with the State Geological Survey has established at the College of Engineering, University of Illinois, Urbana, Illinois, a Mine Explosion and Mine Rescue Station. The purpose of the station is to interest mine operators and inspectors in the economic value of such modern appliances as the oxygen hel-

metts and resuscitation apparatus as adjuncts to the normal equipment of mines. The station also will concern itself with the training of mine bosses and others in the use of such apparatus. Its service is to be rendered gratuitously, and so far as possible, to all in Illinois, Indiana, Michigan, west Kentucky, Iowa and Missouri. The formal opening of the station is to constitute a part of the proceedings of a fuel conference which is to be held at the University of Illinois from March 11 to 13.

ON the first of March, Captain John Donnell Smith, of Baltimore, sent to the Smithsonian Institution the second consignment of his herbarium, consisting of more than seven thousand sheets of ferns. The entire herbarium, consisting of over one hundred thousand mounted plants, together with his botanical library of sixteen hundred volumes, was formally presented to the Institution in 1905.

A GIFT of £1,000 from Mr. C. F. Foster, and of a second £1,000 by Mrs. Rawlins, towards the intended new Archeological Museum, at Oxford, are announced. These sums, like further sums given by the Foster family, who have now subscribed £8,000, are given in memory of Mr. W. K. Foster.

IT will probably be arranged that members taking part in the meetings of the British Association at Winnipeg from August 25 to September 1, may travel at the single fare rate of £7 11s. for the return journey between Quebec or Montreal and Winnipeg. This also applies to side trips in eastern Canada, the local single first-class fare being charged for the round trip, and it holds good for the round trip to points west of Winnipeg, the return ticket to the Pacific Coast points permitting members to return by the Crows' Nest Pass route.

A JOINT resolution passed both houses of congress authorizing the secretary of state to issue an invitation for the eighth International Congress of Applied Chemistry, to be held in this country. All the national societies interested in chemistry, educational institutions, corporations, etc., have been invited

to send delegates to a meeting to be held at the Chemists Club on April 3, to form an organization.

At a meeting of the business committee and the German members of the International Cancer Research Association, held at Berlin, on January 4, it was agreed, on the proposal of Professor von Czerny, to convene a conference on cancer at Brussels during the exhibition in that city. The final decision was left to the board of directors, which will meet during the session of the German Surgical Congress at Berlin, April 14 to 18.

It is expected that the Antarctic exploring steamer *Nimrod* will return to New Zealand at the end of March or the beginning of April. The headquarters of the expedition are at Lyttelton, the port of Canterbury, in the South Island, and that will be the *Nimrod's* destination when she comes out of the Antarctic regions. It is possible, however, that she will touch at a more southern port before reaching Lyttelton. She may put in at Half-moon Bay, in Stewart Island, off the southern coast of New Zealand, or at the Bluff, the southernmost port on the mainland.

THE program of the Forest Club of the University of Nebraska for the second semester is as follows:

February 16—"The Commercial Forest Nursery," by Mr. L. O. Williams.

March 2—"Lumbering in Washington," by E. G. Polleys.

"Microscopic Study of Woods," by G. N. Lamb.

March 16—"Factors Affecting Stream Flow," by Dr. Condra.

March 30—"Formation of Forest Soil," by Professor Barber.

"Moisture Studies in Forest Soils," by Professor Keyser.

April 27—"Scientific Problems in Forest Plantations," by Professor Phillips.

May 11—"State Problems in Wisconsin," by A. G. Hamel.

"Utilization in Wisconsin," by J. C. Ketrledge.

May 25—"Forest Types in the Philippines," by G. Pagaduan.

"Forest Utilization in the Philippines," by M. Lazo.

By signing the bill for the creation of the Calaveras National Forest, California, President Roosevelt has completed the legislative act which saves the most famous grove of trees in the world. The first Calaveras bill was introduced in the senate four years ago by Senator Perkins, of California. Bills for the same purpose were passed in the upper house of Congress a number of times, but failed of favorable consideration in the house. There is to be a practical exchange of the timber in the groves for stumpage on other forest land owned by the government. The land to be acquired under the bill includes about 960 acres in what is known as the North Calaveras Grove in Calaveras County, and 3,040 acres in the South Grove in Tuolumne County. The North Grove contains ninety-three giant sequoias and in the South Grove there are 1,380 big trees. Any tree under eighteen feet in circumference, or six feet through, is not considered in the count of large trees. Besides the giant sequoias there are hundreds of sugar pines and yellow pines of large proportions, ranging to the height of 275 feet and often attaining a diameter of eight to ten feet. There are also many white firs and incense cedars in the two tracts. The North Grove contains ten trees each having a diameter of twenty-five feet or over, and more than seventy having a diameter of fifteen to twenty-five feet. Most of the trees have been named, some for famous generals of the United States and others for statesmen and various states of the union. "The Father of the Forests," now down, is estimated by Hittel, in his "Resources of California," to have had a height of 450 feet and a diameter at the ground of more than forty feet when it was standing. "Massachusetts" contains 118,000 board feet of lumber; "Governor Stoneman" contains 108,000 board feet, and the "Mother of the Forest," burned in the terrible forest fire which licked its way into a part of the grove last summer, contains 105,000 board feet. Each of these trees named grows as much lumber as is grown ordinarily on fifteen or twenty acres of timberland. The bark runs from six inches to two feet in thickness.

It is said that the Ohio State legislature once passed a bill establishing the value of π to accord with the views of some circle-squarer. It is perhaps scarcely fair to put in the same class the bill now before the British parliament. This bill "to promote the earlier use of daylight in certain months yearly"—formerly known shortly as the Daylight Saving Bill—is down for a second reading in the House of Commons. The operative clauses of the bill, as summarized in *Nature*, are as follows: (1) From two o'clock in the morning Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the *third Sunday in April* in each year until two o'clock in the morning, Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the *third Sunday in September* in each year the local time shall be in the case of Great Britain one hour in advance of Greenwich mean time and in the case of Ireland one hour in advance of Dublin mean time, and from two o'clock in the morning Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the *third Sunday in September* in each year until two o'clock in the morning Greenwich mean time in the case of Great Britain, and Dublin mean time in the case of Ireland, of the *third Sunday in April* in each year the local time shall be in the case of Great Britain the same as Greenwich mean time and in the case of Ireland the same as Dublin mean time. (2) The time hereby established shall be known as summer season time in Great Britain and Ireland, and whenever any expression of time occurs in any Act of Parliament, deed, or other legal instrument, the time mentioned or referred to shall, unless it is otherwise specifically stated, be held in the case of Great Britain and Ireland to be summer season time as prescribed by this Act. (3) Greenwich mean time as used for the purposes of astronomy and navigation shall not be affected by this Act. (4) This Act shall apply to the United Kingdom of Great Britain and Ireland, and may be cited as the Summer Season Time (Great Britain and Ireland) Act, 1909.

THE Dove Marine Laboratory at Cullercoats, which is to be occupied as a department of the Armstrong College, Newcastle-on-Tyne, was opened on December 29 by the Duke of Northumberland. From the account in the *London Times* we learn that the new building, which stands on the site of the old baths, contains an aquarium 80 feet by 23 feet, and there are 11 fish tanks. There is also a private aquarium, and provision is made in 36 tanks for the storing of materials for the workers for experiments, hatching and the like. Against the west wall is a concrete tank holding 15,000 gallons of salt water, which will give a continual flow through the various tanks, etc. In the center of the west gable is the coat of arms of the Hudleston and Dove families, and a polished granite tablet near the entrance bears the inscription: "Erected A.D. 1908 by Walter H. Hudleston, M.A., F.R.S., for the furtherance of Marine Biology and as a Memorial of his Ancestress Eleanor Dove." Mr. W. H. Hudleston, the donor of the building, presided. The Duke of Northumberland congratulated the people of Cullercoats on the new laboratory. He said there was one at Plymouth, one at Port Erin, in the Isle of Man, one in Lancashire, and three in Scotland, and the new building opened that day enabled them to fill up the gap. If they were to study the habits of fish and to give advice to those engaged in the industry, it was absolutely necessary to have these laboratories scattered up and down the coast. The county council of Northumberland was willing to contribute £100 per annum to that institution. It was willing to do more and to double that amount if the borough of Tynemouth came forward and subscribed £50. The duke paid a tribute to the generosity of Mr. Hudleston and to Professor Meek, who is to have charge of the laboratory.

At the thirty-first annual general meeting of the Institute of Chemistry, held at 30, Bloomsbury-square, W. C., Professor Percy F. Frankland, the retiring president, in the course of his address, said, as reported in the

London *Times*, that the roll of the institute had increased by 78 fellows, 30 associates and 68 students, and, notwithstanding the increasing stringency of the regulations, the number of candidates for examination had increased from 94 in 1906 to 150 in 1909. He believed these figures indicated that a real advance was taking place in the demand for highly-trained chemists. It was one of the chief duties of the institute to maintain a high level of training for professional chemists by demanding of candidates for its membership evidence of thorough training, and by requiring them to pass searching examinations. He yielded to no one in the advocacy of research as a part of training; there was however much training in originality of thought and experimental procedure which was not called research and much of what was called research that involved no originality in the thought or deed. He then stated that a special committee had been discussing the arrangements to be made in view of the approaching expiry of the lease of the present premises of the institute and had come to the conclusion that between £10,000 and £15,000 would have to be raised by voluntary contributions in order to provide even a modest but dignified home in which the institute could carry on its work. Dr. George Beilby, F.R.S., was elected president.

THE Colorado Desert, in southern California, is one of the most interesting and one of the most nearly rainless parts of the United States. It lies in a wide valley, the northwest extension of the great depression at whose south end is the Gulf of California. Before the overflow of Colorado River into the Salton Sea, which began about five years ago, this basin was, with the exception of Death Valley, the lowest dry land in the United States. It is also the hottest place in the country, according to the official records. Parts of the desert are wastes of shifting sand, kept in almost constant motion by strong winds. Other parts, on the borders of the Salton Sea, contain strongly alkaline areas, and in some places now covered by that sea large quantities of salt have been mined,

South of the Salton Sea, in the Imperial Valley, the soil consists of fine silt, deposited in past centuries from the overflowing waters of Colorado River. This part of the area is the scene of the spectacular and almost uncontrollable overflow which was the occasion of a special message from the President to Congress and which was closed after repeated failures only in 1907, by the Southern Pacific Company. Toward the north end of the valley in which this desert lies, for the most part below sea-level, is the Indio region, or the Coachella Valley, where underground waters have been utilized for irrigating several thousand acres of fertile land. Melons, barley and alfalfa are extensively grown on large areas, and smaller tracts have been planted in oranges, grapes, sweet potatoes and sugar beets. Date palms have been planted also, and on the agricultural experiment station farm at Mecca rare varieties of luscious dates, which heretofore have been produced only in the Arabian deserts and in the oases of northern Africa, are grown successfully. A report on the Indio region, including a sketch of the Colorado Desert, prepared by W. C. Mendenhall, has just been published by the U. S. Geological Survey as Water-supply Paper 225, which may be had free on application. The report includes a description of the geography and geology of the Colorado Desert and an account of the underground waters of the Indio region, and is illustrated by maps, sections and reproductions of photographs of interesting features of the country.

UNIVERSITY AND EDUCATIONAL NEWS

THE passage of the legislative appropriation bill carrying \$982,000 for the University of Kansas, gives the university all it asked, excepting an appropriation for a dormitory.

By the will of Ellen A. Kendall, her residuary estate is given Wellesley College to found a professorship bearing her name. It is provided that if the fund exceeds \$60,000 the income of the excess shall be used to aid worthy students.

THE final settlement of the estate of Archibald Henry Blount, of England, who some time ago made Yale University his residuary legatee, shows that the university will receive net from the estate the sum of \$328,752. In the settlement of the estate there has been paid out \$8,539 for the university's legal expenses in the matter, and about \$70,000 as an inheritance tax to the English Government.

THE Ontario legislature has passed a resolution permitting Toronto University to take advantage of the Carnegie Foundation's pension fund. The legislature of Nebraska has refused permission to the state university.

It is announced that Columbia University will establish a course in forestry leading to the degree of forest engineer. The plan will probably be put into effect next year though the special work would not begin for two more years.

A BILL has been introduced in the New York legislature amending the educational law by providing for the establishment of a State School of Sanitary Science and Public Health at Cornell University.

THREE departments of Sibley College, Cornell University—those of marine engineering, naval architecture and railway mechanical engineering—have been discontinued. This action has been nearly coincident with the departure from Cornell of the heads of two of the departments, Professors C. C. Thomas and H. Wade Hibbard. But these professors did not go because their departments had been or were to be abolished, nor was their departure the cause of the termination.

THE academy in Neuenburg, Switzerland, is to become a university.

THE Egyptian government has in view the establishment of a national university. The theological students at Cairo have recently petitioned for competent teachers of modern science.

At a recent meeting of the faculty of Wesleyan University, two committees were appointed to act with those of the trustees. One in regard to the establishment of a separate college for women has Professors Rice, Win-

chester, Harrington, Nicolson and Bradley as members; the other, which will help fix the date of the inauguration of President Shanklin, consists of Professors Rice, Winchester and Crawford.

ACCORDING to the *Umschau* there are this semester 1077 regularly matriculated women students in the German universities as compared with 140 three years ago.

At the meeting of the board of trustees of Stanford University, on March 5, the following promotions in rank to take effect with the beginning of the academic year 1909-10 were made: To the rank of professor: Frank Mace McFarland, in histology; John Flesher Newsum, in mining; Harold Heath, in zoology; Arthur Martin Cathcart and Wesley Newcomb Hobfeld, in law; James Farley McClelland, in mining engineering; Guido Hugo Marx, in machine design; Henry Waldgrave Stuart, in philosophy. To the rank of associate professor: Karl G. Rendtorff and William Alpha Cooper, in German; Lillian Jane Martin, in psychology; Raymond Macdonald Alden, in English; William Rankine Eckart, in mechanical engineering; Halcott Cadwalader Moreno and Sidney Dean Townley, in applied mathematics; Charles Andrews Huston and Joseph Walter Bingham, in law. To the rank of assistant professor: Payson Jackson Treat, in history; Mary Isabel McCracken and Rennie Wilbur Doane, in entomology; Walter Kenrick Fisher, in zoology; James Pearce Mitchell, in chemistry; Leonas Lancelot Burlingame, in botany.

DR. R. S. WOODWORTH, adjunct professor of psychology in Columbia University, has been promoted to a professorship of psychology. Mr. H. H. Woodrow has been appointed tutor in psychology at Barnard College.

DR. LUDWIG MESSER, associate professor of philosophy at Giessen, has accepted a call to the University at Buenos Ayres.

DISCUSSION AND CORRESPONDENCE

ADULTERATION AND THE CONDITION OF ANALYTICAL CHEMISTRY AMONG THE ANCIENTS

IN an address of Mr. W. D. Richardson published in *SCIENCE* last year, attention is called

to the very speculative condition of ancient science. Mr. Richardson remarks that "Ancient records and books are extremely few in number, and worse than that, the scientific writings, when they are not purely speculative, are quite unreliable." This statement, while undoubtedly true, in a certain sense seems to me open to criticism in that it is apt to give one an entirely mistaken idea of what classic writers have recorded regarding the achievements of the ancients in practical chemistry. As a matter of fact, enough reliable practical chemical knowledge has come down to us in the writings of Pliny, Dioscorides and others to form a very respectable treatise. The "Natural History" of Pliny, for example, is completely interwoven with little digressions upon what is now termed the "chemistry of every-day life" and the reader is often surprised to run across statements, which might have been taken from some modern work, such, for example, as references to the use and well-recognized efficiency of burning sulphur for fumigating and purifying the interior of dwellings (book 25, ch. 50), or to the use of suspended cords upon which to crystallize substances (book 34, ch. 32), or to the lowering of a burning light into wine vats to determine whether or not it was safe for workmen to descend in order to remove the lees. "As long as the light refuses to burn it is significant of danger" (book 28, ch. 31). Pliny's book is filled with such little practical points as these, all of which, together with his description of many technical processes in which the Romans were recognized masters, such as the mixing of mortars and cement, the manufacture of white lead and other pigments, the fermentation of wine, the use of legumes in crop-rotation, etc., serve as a most striking commentary upon the manner in which the practise of a science may anticipate the dictates of its theory—even by thousands of years. Much of the matter which Pliny has gleaned in his "Natural History" was common knowledge centuries before his time. The use of burning sulphur as a disinfectant, for example, is mentioned in the "Odyssey" of Homer (book 22, ch. 481). Odysseus, after

the murder of the suitors, cries out to his aged nurse: "Bring sulphur, old woman, the cleanser of pollution and bring me fire, that I may sulphur the chamber."

The science of the ancients was extremely weak, however, upon its analytic side and in the course of its whole history may be said to have produced but one mind truly great in this respect—that of Archimedes. This philosopher and experimenter by his method of displacement was the first to establish a physical constant—that of specific gravity—and the first to apply such a constant to certain analytical problems as in the well-known example cited by Vitruvius, where Archimedes determined the purity of the gold in King Hiero's votive crown.

The application of specific gravity to the testing of various bodies, liquid as well as solid, seems to have been common after the time of Archimedes. Pliny (book 31, ch. 28), in fact, alludes to the use of some form of specific gravity balance (*Statira*) by which the purity of water could be tested.

The search for a means to detect adulteration was what led Archimedes to his epoch-making discovery and this we will find to be always a leading stimulus in the development of analytical chemistry in ancient as well as in modern times. The adulteration of foods and other commodities of life was as common in the early days of the Roman Empire as it is to-day. Pliny repeatedly calls attention to the many frauds of his time. "It is the natural propensity of man to falsify and corrupt everything," he exclaims while writing of the adulteration of honey, and again, when speaking of the use of gypsum, pitch, lime, rosin, wood ashes, salt, sulphur, artificial pigments, etc., for treating wines (book 14, ch. 25), he cries out: "By such poisonous sophistications is this beverage compelled to suit our tastes, and then we are surprised that it is injurious in its effects!" Pliny blames the druggists especially for their practises in this respect and is most bitter in his denunciations of the whole fraternity of Roman apothecaries. Many pages of the "*Naturalis Historia*" are in fact devoted to the disclosure of the

"shady" practises carried out in the shops of the ancient druggists (*tenebræ officinarum*).

In the long list of tests, which Pliny enumerates for detecting the various forms of adulteration practised in his time, by far the greater number relate to the use of our simplest sense perceptions, such as taste, smell, color, feel, brittleness, etc. The ancients guided by such perceptions were unquestionably better judges of the purity of many articles of food than we are to-day. Pliny in fact, makes such a fine classification of tastes and flavors (book 15, ch. 32) that the translator finds himself at a loss for suitable terms in which to express the meaning. Whether this indicates an over-refinement of the taste perception among the Romans through the influence of a long line of epicures dating from Lucullus, or simply an atrophy of our present powers in this respect, would be difficult to say. Professional tasters (book 14, ch. 8) were in demand during the early days of the Roman empire to determine the quality of wines, and notwithstanding our advanced chemical knowledge of the score or more esters which give wines their characteristic bouquet, the final criterion in the judgment of a wine, now as in the days of Pliny, is the evidence of a skillful taster.

But the ancients had many other means of testing the purity of their commodities of life than those of simple taste and smell; and it is worth our while to examine a few of these, for they mark in reality the first beginnings in the development of the science of analytical chemistry. A good illustration of such tests is given under Pliny's description of Balsam (book 12, ch. 54).

Balsam in a genuine state should be quite hard, but when it is mixed with gum a brittle pellicle forms upon it. The fraud can also be detected by the taste and when placed upon hot coals it may easily be seen if there has been any adulteration with wax and rosin, for the flame in this case burns with a blacker smoke than when the balsam is pure. In addition to these various tests a drop of pure balsam, if placed in luke-warm water, will settle to the bottom of the vessel, whereas, if it is adulterated it will float upon the surface like oil, and if it has been drugged with *metopion* or *am-*

moniacum, a white circle will form around it. But the best test of all is, that it will cause milk to curdle, and leave no stain upon cloth.

Such tests as the ones cited in this quotation show that the faculty of careful and precise observation was by no means neglected among the ancients.

The flame test to which reference was made, is mentioned repeatedly by Pliny in the testing of drugs and chemicals. In some cases the color and smell of the smoke were observed, in others the color of the flame, or the property of decrepitating.

The formation of a white ring as described by Pliny in his test for adulterated balsam, brings up to the mind of the chemist the innumerable ring tests which are made use of in the laboratory at the present day, as well as the host of color reactions employed in testing food products, drugs and chemicals. We find, in fact, that these color reactions were used very extensively by the ancients, and the mention of one or two others may have a passing interest.

Among the tests given for alum Pliny (book 35, ch. 52) states that it will turn pomegranate juice and nut galls black. Authorities differ somewhat as to the exact nature of the compound that was called *alumen* by the Romans and *στυπτηρία* by the Greeks, but all seem agreed that sulphate of iron was present. The tests which Pliny describes are therefore nothing but the familiar tannin reaction with salts of iron.

A most interesting modification of the nut-gall test is described under the subject of verdigris (book 34, ch. 26). Here a piece of papyrus, which had been previously steeped in an infusion of nut galls, is employed for testing, the paper so treated turning black if genuine verdigris is applied. This passage is noteworthy, for so far as I can find it is the first historical reference to the use of test paper.

In a number of instances I have found Pliny to be even wiser than his modern commentators. Pliny gives, for example, as one of the tests for vinegar (book 23, ch. 27) that it has the property of effervescing when poured upon the ground. The editor of one

translation remarks as to this that the vinegar of the present day does not have any such property. If this commentator, however, had had even a little knowledge of chemistry, he might have remembered that the acid of vinegar may cause a considerable effervescence of carbonic acid when brought into contact with chalky or calcareous soils.

In testing the purity of minerals and precious stones the ancients seem to have acquired considerable dexterity. The use of the touch-stone (Coticula) for determining the purity of precious metals and their ores was well known to the Romans and employed with such accuracy, according to Pliny (book 33, ch. 43), that the proportion of gold, silver or copper could be told instantly, even to the smallest fraction. In detecting the imitation of gems and precious stones—concerning which Pliny (book 37, ch. 75) states that most colossal deceptions were practised and in no other kind of fraud greater profits made—the ancients were in many ways as skillful as the jewelers of to-day. They employed the balance, tested certain optical properties, and even used a scale of hardness (book 37, ch. 76), it being recognized that some stones could be scratched with a blunt knife, while others could not be marked with the hardest obsidian.

Lack of space forbids giving other examples of the methods employed by the ancients in testing the purity of the commodities of life. The examples cited however show that the fragmentary records of ancient science preserved by Pliny, full as they are of inaccuracies and absurdities, contain a large amount of reliable chemical knowledge. And if the 474 authors whom Pliny consulted in the preparation of his "History" had come down to us intact we may be sure that our knowledge not only of historical, but also of practical, chemistry would be greatly enriched.

NEW YORK

EVOLUTIONARY COLLECTIONS AS MONUMENTS TO DARWIN

TO THE EDITOR OF SCIENCE: In connection with the recent announcements that special

collections in honor of Darwin are to be formed at the American Museum of Natural History, and that Haeckel intends to devote the remainder of his life to his phylogenetic museum, I venture to call attention to the subjoined selections from my address, "Educational Museums of Vertebrates," before the Biologic Section of the American Association for the Advancement of Science in 1885 (see the *Proceedings*, vol. 34, and abstract in SCIENCE, September 11, 1885):

A statue of Darwin has been unveiled in London with honorable ceremonies. What monument to his memory could be more appropriate or lasting than the formation, in all educational institutions, of collections especially designed to exhibit the facts which he made significant, and the ideas which his knowledge, his industry and his honesty have caused to underlie the intelligent study of nature throughout the world. Such collections should particularly embrace series illustrating human peculiarities, not only as to skeleton, but as to brain, heart and other organs; human resemblances to mammals in general; features that unite man with the tailless apes, and separate them from all other mammals; transitory human organs and conditions that resemble the permanent organs and conditions of other mammals, especially apes; human anomalies resembling the normal structure of apes; anomalies and malformations affecting man and other vertebrates in a similar manner; apparently useless or detrimental organs or conditions.

BURT G. WILDER

ITHACA, N. Y.,

February 13, 1909

QUOTATIONS

THE FUTURE OF YALE

If I were president of Yale! But that is inconceivable. I was never in the hereditary line of descent. Besides I stepped out of all other lines that tend toward New Haven when, forty years ago, after getting more or less ready for Yale, I went as a pioneer to untried Cornell. I went because botany and geology and European history at Cornell counted for as much as Latin or Greek; and now I have to take the consequences.

If I were president of Yale, and had the necessary power and the necessary backing, this I would surely do. I would make it Yale College or else Yale University. For the questions would lie heavily on my conscience—Should a boy go to a university for college work? Should a man go to a college for university work? Should a school for boys try to teach also men? Should a school for men teach also boys, under the same conditions and regulations, and with the same teachers?

I read not long since a well-written book, "What College for the Boy?" In this volume, Yale College receives favorable mention, and most justly. Can I imagine a cognate volume in Germany? "Welche Universität für den Knaben?" The very title is absurd on the face of it, for the place of "Knabe" is not in the "Universität." Conversely, the function of a university is not to teach the boy but the man.

The name "university" has in Germany and in continental Europe a fairly definite meaning. In America, it means nothing in particular, except a higher school, higher than the high school. In England it often means still less—an examining board authorized to confer degrees. Let us take the German meaning—a school for men, who have finished their general culture, have ceased to be boys, and have begun preparations for life work as professional men, as teachers or as investigators. This is the meaning Johns Hopkins has brought to America, and which is recognized as a valuable but exotic attachment at Harvard, at Yale and with the rest of us.

On the other hand, we have adopted the English term "college" for a group of schools progressively diverging from the English standards, but which agree in this. Their first function is to make men out of boys, and to secure the boys' cooperation and interest in the process. Where this is best done is in the "college for the boy." Where the demands of scholarship are most strenuous, where expeditions are constantly undertaken for the conquest of the unknown, where books, apparatus and collections are greatest, that is the university for the man.

In this transition stage, we have lost sight of both ideals. Rather, we behold one of them for a time, then the other, and we rush like a school of herrings toward the light that we see for the moment.

A few years ago, almost every college pretended to be a university. Almost every college teacher thought himself engaged in research and pretended to hold in contempt the "boy" and all his own duties toward the boy. So the boy became estranged from his work, and made trouble. Thus the college ideals are again insistent. Good teaching is again the demand, and the tireless attention to details that make boy-training possible, and which shut out the teacher from research of any intensive character.

All honor to the college teacher who in all these years has never lost his head, and who has steadily, consistently and without self-compromise done his duty in making boys into men. He finds them just as plastic as they ever were, and his reward as ever is in the doing.

All honor to the university teacher who abates none of his ideals, who sees the universe with a keener eye than the rest of us, and who never forgets his first duty as a seer, a prophet, a founder of a school of thought, a leader of men.

The college and the university are here, are here to stay, and here to grow and develop; but not in the same space, and still less as, at present, telescoped together. Sooner or later, we must recognize the two different functions. Sooner or later we must see that the college with its boy's play, its foot-ball team, its glee club, its need of personal inspiration, its need of rigorous moral discipline, its need of absolute inhibition of vinous conviviality, its demand for insistent training rules to prevent grafting and dissipation, is an end in itself. The glory of Yale has been that of Yale College, and Yale will have fulfilled all that a nation can ask of it if it makes Yale College the culmination of its activities. Or, Yale University may be the glory of the future—the thorough professional and technical training of men already broad-minded, clean-souled, and well-

grounded in all that the college can give in its four years of fellowship, aspiration and discipline. (These four years ought to end as they did thirty years ago, with the year we now call "sophomore," but that is another story.) But Yale College and Yale University, all together and equally great, that can never be.

Yale University needs books, apparatus, collections, long-striding scholars and founders of dynasties of scholarship and research. Yale University needs millions; Yale College has enough. But Yale College and Yale University in one yard, under one body of teachers, under one set of discipline, and forever getting in each other's way; this condition can never be a finality. Until they are separated in space, as in time, Yale College can not escape the reproach all our colleges bear, that she neglects her boys in the imagined interest of research; that her professors do not love their work, and slight it in many ways; that if the boy becomes a man the college deserves no thanks for it.¹ On the other hand, Yale

¹Says Dr. George E. Vincent, a dean of the University of Chicago: "The chief causes which are alleged to be responsible for a perceptible lowering of the standard of student work are: less definite and disciplinary instruction in the elementary and secondary schools; an elective system permitting a haphazard, desultory, individual course; the presence of an idle rich class setting a standard of ostentation and luxury; the exaltation of competitive athletics and the heroizing of successful athletes; the growth of fraternities with their time-consuming activities and social distinctions; the emphasis on social life and the consequent prejudice against the diligent student who takes little part in the 'valuable education outside the classroom'; the over-crowding of classes so that attention to individual students is difficult or impossible; the introduction of the lecture system for undergraduates accustomed to the drill of the recitation method; the putting of young, inexperienced, overworked and illpaid instructors in charge of freshmen and sophomore divisions; the competition between instructors in offering popular, largely elected, and too often 'snap' or 'soft' courses; the exaltation of research at the expense of 'mere teaching' and the consequent lowering of teaching efficiency; the extension of the doctrine of freedom

University will find itself blamed for contributing so little to the advance of knowledge. With a staff as large as that of Leipzig, more or less, and an equivalent student body, its scholarly output is less than half that of the German institution. This sort of criticism we hear again and again. Whether this be just or not is a minor question. People think that it is true, and it will be essentially true so long as Yale College is interchangeable with Yale University.

Were I president of Yale, I would cling to the one ideal or the other, letting all else go. For the time must come when our colleges can not fulfill our university ideals, by adding scantily equipped professional schools and hiring a dozen or two graduate students to shift for themselves under overworked professors. Meanwhile, our universities can not make men out of boys unless they address themselves most seriously to the business, "bringing every ray of various genius to their hospitable halls" that through their united influence "they may set the heart of the youth in flame."

You will see that this applies to Yale no more and no less than to Harvard, to Cornell, to Wisconsin and to any other institution which is trying to do boy's work and man's work at the same time, in the same place, and by the same educational machinery. We have just now referred to the University of Leipzig. Let us suppose that to her three thousand students, more or less, she should add as many more from the higher grades of the gymnasium or high school, corresponding to our freshmen and sophomores. Let us suppose that she should add to her faculty of three

of teaching to protect a careless or inefficient instructor of elementary courses from investigation; failure to make college work seem vital to the student, a means to his personal ends, in marked contrast with the success of the professional schools which hold up a definite goal, arouse interest and enforce a higher standard of effort and accomplishment. The mere enumeration of these charges raises many questions of fact and interpretation. That some if not all of the influences are present in all of our colleges is not to be denied."

hundred professors, more or less, as many gymnasium drill masters. Let us suppose that the resultant multitude were called a university. It would be just the same sort of a university we have developed in America, a place where men and boys are gathered together, each in the other's way, and where neither ideals of scholarship nor ideals of man-making can reach their most perfect achievement.—President David Starr Jordan, in *The Yale News*.

SCIENTIFIC BOOKS

Conditions of Life in the Sea. A Short Account of Quantitative Marine Biological Research. By JAMES JOHNSTONE. Pp. 382. Cambridge Biological Series, Cambridge University Press. 1908.

Many good things must be, and a few bad things ought to be, said about this book. Since it is more agreeable to speak well than ill, we will occupy ourselves first and chiefly with what is good.

The broader value of the work is two fold.

In the first place it affords an easy, reliable opening into an important, rapidly growing field of knowledge that hitherto has not been readily accessible to general readers, nor indeed to special scientific students. The field to which reference is made is marine biology as developed particularly by the countries bordering on the North Sea. Many professional biologists, especially in America, have not yet had brought home to them the fundamental nature of various conceptions and methods involved in these investigations.

In the second place the book is noteworthy for biology generally from the consistency with which the quantitative standpoint is maintained. The reviewer does not recall another semi-popular work in which organisms are regarded in a quantitative way for so wide a range of their relationships. In this the book may be looked upon as a harbinger of what biological treatises of general character will be in the future. This statement tells at once that the author is enrolled in the so-called Hensen or Kiel school of marine biologists.

Much criticism has been passed upon both

the methods and results of this school. One may be indeed justifiably sceptical concerning the value of the particular calculation that a square mile of the water of the Baltic Sea contains 80 to 100 billion copepods, or that there were 180,189,000 haddock in the whole North Sea during the spring of 1895. The chief interest in the calculation lies in its significance concerning what biology's attitude toward its problems may be. In a given limited area of the ocean, the North Sea for example, there is at a given time *some* limited number of haddock. Finite quantities of substances and bodies and forces are the very foundation stones of all physical science, biology with the rest, and sooner or later as knowledge advances, values for these quantities are bound to be sought. When fishing industries unite with clearly perceived biological problems in demanding information as to how many herring there are in the North Sea, and how much food is available for them, to get such information is exactly part of the business of science. If the first attempts are not sufficiently reliable, others with better methods must be made. For biology to take the ground that such researches can not be successful, nor would be significant if they were, would be to acknowledge itself stunted in its early youth.

The book is divided into three parts. Part I. designated introductory, contains in the first place a general description of the apparatus and procedures used in the most advanced marine biological researches. An account of certain aspects of oceanography is also given as is a very general survey of the Life of the Sea. Such topics as bottom deposits, composition, temperature, transparency and circulation of the waters are touched upon.

Under the heading Life in the Sea the zones of littoral life, bottom dwellers, or the benthos, and the free life, or the nekton and plankton, and kindred subjects are spoken of and several figures showing characteristic pelagic invertebrates and algae are given. This part ends with a chapter on sea fisheries.

The real essence of the volume is in parts II. and III., designated respectively Quanti-

tative Marine Biology and Metabolism of the Sea. Part II. is, on the whole, the most satisfactory portion of the book. The author is at his best when dealing with actual observations and matters of fact in such a way that his general biological theories have no visible influence on his conclusions, and it is unfortunate that the whole book could not have been written with a mind thus unhampered.

Although Mr. Johnstone's adherence to the Hensen ideas is unqualified it is not slavish. Most, though by no means all, of the more telling criticisms passed upon the methods and results of the Kiel school are duly heeded. The methods of collecting developed up to date are treated to the extent of nearly ten pages, and Lohmann's interesting observations on the capture of plankton by appendicularia is adequately noticed. The four methods of estimating the quantity of plankton, viz., the volumetric, chemical, gravimetric and numerical, are considered both as to processes and reliability. Of these "the actual counting of the organisms is the most satisfactory."

The surface distribution of certain kinds of planktonic organisms in the north Atlantic is illustrated chiefly by reference to Cleve's work. Two instructive charts accompany this discussion.

A chapter devoted to A Census of the Sea, and another on The Productivity of the Sea, summarizes considerable of the data on these subjects, though by no means all that has been gathered by the investigators of the north Atlantic.

On the question of the depletion of the sea through fishing, the author, though admitting the absence of conclusive proof on either side, and noting the authoritative opinion against exhaustion, thinks "we can not come to any other conclusion than that fishing operations as at present carried on, do cause a very appreciable diminution of the stock of fish on the sea bottom." More reliance is placed on Hensen's investigations than on any others for this conclusion.

Greater productivity of the ocean in high latitudes than in low is regarded by the author as proved. The three chief explanations

of this supposed fact are considered in part III. Brandt's conjecture that denitrifying bacteria are more active in warmer waters and hence prevent these from containing as ample a supply of nitrogenous food-salts for the phyto-plankton as the colder waters have, is held to be "not the only hypothesis capable of explaining" the phenomenon. Nathanson has suggested that in some localities at least, colder waters may contain greater quantities of organic matter because they have up-welled from the bottom or deeper water where such matter has gradually accumulated through the settling into them of the carcasses of organisms that have lived in the lighter waters above; or through the transference to them by convection-currents of warmer surface water from middle latitudes that have been enriched in organic matter by rivers from land areas clothed with vegetation of tropical luxuriance. Johnstone thinks this hypothesis worthy of consideration.

Finally the explanation proposed by Pütter is presented. This author supposed, to state the case in a nutshell, that animals inhabiting warm waters live faster than those inhabiting cold waters and so consume more food. Consequently since the food supply is everywhere limited, a less numerous population can be maintained in the warmer than in the colder seas.

Among the many interesting subjects treated in part III., none is more interesting than that of nitrogen in the sea and the relation of bacteria to this element.

That imagination would be dull indeed that should not be kindled by the picture outlined in this part of the book of what the earth really is as a habitation for living beings. The truly cosmic character of the problems the threshold of which has been crossed by Brandt and the few other foremost investigators in this realm, is well brought home to the reader.

The book ends with several useful appendices, one of which is a summary of A. B. Macallum's interesting though not convincing speculations on the chemistry of the early seas, and the impress this has left on living beings down to even the present.

It remains now to point out certain really bad defects in the work. In the first place the title is misleading. From it a prospective reader would anticipate a comprehensive treatise—comprehensive, that is, in the sense of reaching to the seas of the earth generally. As a matter of fact the only indication the book contains that the author knows of the existence of oceans beyond that contiguous to northwestern Europe is just enough reference to others to impress the reader with the idea that whatever such there chance to be, may be ignored, except so far as they illustrate the central truths, truths, that is, that center in the North Sea. Think, for instance, of a discussion of "The Productivity of the Sea" that does not mention the cod-fisheries of Newfoundland, the salmon-fisheries of Alaska, and the fisheries generally of Japan and China!

How shall a professedly general treatment of the problem of the depletion of the sea be characterized that makes no reference to the Alaskan salmon hatcheries or to the perennial effort to save from destruction the fur-seal herds of the Behring Sea?

Had the author taken as his title "Conditions of Life in the *North Sea*" or something of the sort, he would have saved himself from the grave criticism that must now be passed upon him. Any moderately informed reader will surely ask: Does the author not know what has been and is being done in other parts of the world on many of the problems considered, or knowing does he deliberately ignore? Desiring to be fair which alternative shall we reject as being the less creditable?

Is an author's deficiency professional or ethical, which permits him to discuss in a general book the "Stratifications of the Plankton" and make no reference to the work of Alexander Agassiz?

Professor W. A. Herdman and his colleagues of the Marine Biological Association of Liverpool have contributed importantly to the knowledge of the sea and its life, particularly of the western British seas. Does Mr. Johnstone find nothing here deserving

mention beyond the fact of footnote value (p. 191), that Herdman has made "some interesting suggestions as to the use of copepoda as human food?"

Wherefore the book's deficiency in the use of accumulated knowledge? The candid, measurably informed reader is forced to this question over and over again.

Some of the chapters were turned over to the printer while their English was yet sorely in need of pruning and finishing.

On account of the limited amount of food yolk development is a rapid process and the little fish usually hatches out from the egg in a week or two, but is a very feeble and helpless creature (p. 83). (37 words.)

On account of the limited food-yolk development is rapid and the little fish usually hatches in a week or two, but is very feeble and helpless. (27 words.)

Ten useless words in thirty-seven are too many. They make twenty-seven per cent. of superfluity. On the score of mere physical loading this is unfair to the printer, the purchaser and the reader, to say nothing of the writer. Furthermore, there are the literary proprieties. Surely they deserve some consideration even at the hands of the scientific man. True no great number of sentences are as hypertrophied as is this, but it is by no means unique and those that approach it are not rare.

Despite these unsavory remarks brought upon itself, the book's merits far outweigh its defects. All English speaking people interested in the larger aspects of marine biology should feel grateful to Mr. Johnstone for having written it even though they can hardly help wishing he might have made it better in some respects.

WM. E. RITTER

Manual of Practical Assaying. By the late H. VAN E. FURMAN, E.M. Revised and enlarged by WILLIAM D. PARDOE, A.M., Assistant in Mineralogy, Princeton University. Cloth, 8vo. Pp. xi + 497. Price \$3.00.

It was most gratifying to find that this book, which has been considered as a standard, and had been used extensively as a text-

book in nearly all our universities, was not to be permanently laid on the shelf. The friends of Professor Furman heard of his demise with the deepest regret, and it was with the greatest of pleasure that the writer learned that a lasting monument to his name was to be erected through the publishing of a sixth edition on "Assaying," revised and enlarged by Mr. W. D. Pardoe.

This book has been, and will continue to be, the standard on assaying for technical chemists, and for students in the universities which have a mining, metallurgical or any course on the quantitative determination of metals and their associated elements.

The aim of the author was to present to technical chemists and students of chemistry a *practical* book. That he succeeded is demonstrated fully by the demand for a sixth edition. In this book only the most approved methods of analysis have been chosen, and particular attention has been paid to rapid methods which are so indispensable to technical chemists employed on commercial enterprises. At the same time slower and more accurate methods are nearly always given, so that the analyst can use either, according to the dictates of the time at his disposal.

By the revision of the chapters on zinc, water and coal analyses, and the addition of methods for telluride ores, tungsten, molybdenum and vanadium, together with other minor changes, this book has been most thoroughly brought up to the present practise common in most of our large commercial laboratories.

The whole book is singularly free from lengthy theoretical discussions of the reactions taking place, but enough of the reasons "why" are given to enable the trained chemist to understand fully the methods he is pursuing. At the same time the chemist's assistant who may lack a college training can easily pick up "Assaying" and do good work if he follows carefully the very explicit directions.

If the writer may be allowed a word of friendly criticism, since the text is very clear and leaves little to be improved upon, it would seem in some cases as though this text

could have been supplemented to a very great advantage to the student if more diagrams and illustrations of apparatus had been interpolated. For example, a picture or diagram of the quite complicated apparatus, such as is used for the determination of total carbon in the analysis of iron and steel, would go a long way toward helping the beginner in quantitative analysis to fully understand its setting up.

But taken altogether, the book is most admirably adapted for the teaching of assaying in a practical way, and is a most desirable addition to the chemist's library, be he beginner or an expert.

HENRY C. BOYNTON

TRENTON, N. J.

A Study of Splashes. By A. M. WORTHINGTON. With 197 illustrations from instantaneous photographs. London and New York, Longmans Green & Co.

"This publication," as the author says in his preface, "is an attempt to present in a form acceptable to the general reader the outcome of an inquiry, conducted by the aid of instantaneous photography, which was begun about fourteen years ago. . . ."

Every observant person must have at some time or other been impressed with the curious appearance of the splashes produced by rain drops falling into still water: the small pits or craters with little fountains in their centers, which sometimes rise above the surface to the height of an inch or more, can hardly fail to have attracted the attention of every one. In this book we find a collection of some of the most interesting photographs ever obtained by the aid of instantaneous photography. It is a volume of interest to old and young alike, and should be in the hands of every boy interested in natural phenomena. Some of the phenomena recorded by the instantaneous flash of the electric spark can be seen by ordinary eye observation. If a drop of milk is allowed to fall from a height of fifteen inches into a cup of tea or coffee, to which milk has not been added, observation shows us that the white drop appears to penetrate a short distance.

into the dark liquid and then bounce out again. To find out what really happens we have only to inspect the photographs of the drop as it enters the liquid. It forms a hollow bowl or crater six or eight times its own size (in diameter), the milk flowing up the steep sides in radial streams; surface tension then pulls down the walls of the crater, the milk streaming back from all sides towards the center of the crater from which a fountain rises, carrying the reconstructed milk drop upon its summit.

Even more interesting is the study of the difference in the nature of the splash in the case of a highly polished marble and one which has had its surface roughened with sand paper. In the former case we have what Worthington has named the "sheath" splash, which is characterized by a very curious flowing up of the liquid around the surface of the sphere as it enters the water, the marble entering the liquid with little or no sound and the production of no bubbles. If the surface is roughened the liquid does not glide up the surface but shoots off tangentially to the sides, forming the "basket" splash, which is distinctly audible, and is followed by a violent bubbling of the liquid. The author advises every one to have a bag of marbles hung up in the bath-room, and repeat these experiments in the bath-tub. In addition to the wonderfully interesting photographs there is much valuable and entertaining descriptive matter, and the theory of the phenomenon of the splash is very fully discussed in its relation to surface tension, gravity, viscosity of the fluid, etc.

As the author points out a kinoscope capable of securing a continuous series of pictures showing all of the various phases of a single splash is much to be desired. Such an instrument ought not to be difficult to construct. It would not be necessary to have the film brought to rest for each exposure, as is the case in the ordinary instrument, provided the illumination was effected by properly timed electric sparks. The most interesting stages of the phenomena are over in about two tenths of a second, and it would be necessary to secure about one hundred photo-

graphs during this space of time. When run through the machine at the rate of seven per second we should have a quarter of a minute to study the phenomenon. The sparks could be timed by putting a make and break in the primary circuit of an induction coil, so arranged as to be operated by the mechanism which carried the film along.

SPECIAL ARTICLES

A NOTE CONCERNING INHERITANCE IN SWEET CORN

IN the polymorphic species, *Zea mays* L., the sweet corns, called *Zea saccharata* by Sturtevant, have been considered as a single subspecies group characterized by a hard, translucent and more or less shriveled condition of the endosperm. Correns¹ has shown that this character is due simply to an inability to complete the formation of normal maize starch, and further, that the presence and absence of this starch-forming ability act as an independent character pair in inheritance. No other feature is peculiar to the group: varieties characterized by black aleurone cells, red pericarp, yellow endosperm and the other salient points common to dent and to flint corns, are all found in the sweet corns. Their claim as a subspecies group thus rests entirely on the first-mentioned character.

The following evidence, however, indicates that sweet corn varieties do not belong to a unit group, but consist both of dent corns and of flint corns which have lost their original starch-forming power. This condition may have come about through mutation in each of these groups, but from what we know of the early history of the sweet corns, it is more likely that the change took place among the flint types and was extended by hybridization.

The dent corns are distinguished by a cornaceous starchy part of the endosperm which lies at the sides of the kernel and surrounds

¹ Correns, C., "Bastarde zwischen Maisrassen mit besonderer Berücksichtigung der Xenien," *Bibliotheca Botanica*, 1901.

a zone of white starchy matter extending from the tip to the cap, where it forms a layer varying in thickness in different varieties. The shrinkage of this cap starch forms the indentation of the kernel. In the flint corns this soft starch at the cap is replaced by corneous starch, thereby giving the outer portion of the kernel a smooth appearance. Besides this absolute difference, most dent and flint varieties differ in other characters, although a few intergrading strains are found. In the first place, dent corns are found that possess from twelve to twenty-eight rows of kernels, while the older flint types have but eight rows. It is true that there are genuine dents and true flints that tend toward the production of twelve rows, but below this number with the dents, and above it with the flints, continual reversions indicate a hybrid condition. Dent corns are little given to tillering, while with flint corns it is characteristic. This trait is partly a physiological reaction due to the greater amount of soil fertility required by the large main stalk of the dent varieties, and partly an inherent trait capable of hereditary transmission. Flint corns are further characterized by the manner in which the ends of the spathaceous bracts (husks) enclosing the pistillate flowers are expanded into leafy parts from one to two feet long. In the dent corns these appendages are absent or only slightly developed.

The bearing of these opposite features in the dent and the flint corns on the matter in hand, is that *sweet corn with its numerous varieties runs the whole gamut of these characters*. Stowell's Evergreen, a large sweet variety with from sixteen to twenty-four rows, is an example of a "dent" sweet corn, while the Golden Bantam and Black Mexican, two small eight-rowed varieties, are examples of "flint" sweet corns. These varieties are typically dent and flints, respectively, in every character except starchiness. Moreover, when the character of starchiness is brought into kernels of these varieties by pollination with either dent or flint pollen, the hybrid kernels formed are indistinguishable from pure dent and pure flint kernels, respectively. It seems to make no difference with either variety

whether dent or flint pollen is used, for, although the starchy character appears in the individual kernel as *zenia* through double fertilization, the dent and flint characters appear to be largely—I do not say entirely—determined by the plant character possessed by the female parent.

To determine whether Black Mexican sweet corn carries the "flint" character even though it has no "starch" character, it was crossed on a white dent variety. Both types were pedigreed corns; that is, they had been grown in isolated plots for at least five years, consequently they may be considered to have been pure. To remove all doubt on this point, however, kernels from the same ears that produced the plants that were crossed were inbred. The inbred ears all proved to be true to their respective characters.

The F_1 generation of this cross, although it showed the regular Mendelian ratio of starchy and non-starchy kernels, consisted both of dent and of flint ears. Neither the flint character nor the dent character was dominant, hence the appearance of the two types. We are forced to the conclusion that the flint character was brought into the combination by the sweet corn parent, and became manifest when it met the "starch" character of the dent corn parent. In like manner Stowell's Evergreen was shown to carry the "dent" character, by crossing with an eight-rowed starchy flint variety. The F_1 generation contained several dent ears which could only have been produced by the "starch" character of the flint variety meeting the "dent" character of the sweet variety.

It is evident that the internal structure of the corn kernel is based upon several unit characters. There are different patterns of corneous starch which produce pop, flint, dent and starchy varieties. These units seem to be partly independent and partly dependent on starchiness and on shapes of pericarp.

It may also be noted that evidence is accumulating that the above facts regarding sweet corn are largely accountable for the marked superiority in sweetness of most small sweet corn varieties. The "dent" sweet va-

rieties require a longer time between pollination and the date they reach table condition than do the "flint" sweet varieties; and during this time the former kinds appear to change more of their carbohydrate compounds to starch.

CONNECTICUT AGRICULTURAL
EXPERIMENT STATION

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
SECTION B—PHYSICS

THE annual meeting of the American Association for the Advancement of Science, Section B, was held in the Physical Laboratory of the Johns Hopkins University, at Baltimore, December 28-31, 1908. This was a joint meeting with the American Physical Society. Each organization held a short session for the transaction of routine business, but the eight sessions for the reading of papers were joint meetings of the two societies.

The presiding officers were Professor Karl E. Guthe, vice-president and chairman of Section B, and Professor Edward L. Nichols, president of the American Physical Society. Professor F. E. Nipher was elected a member of the council, Professor G. F. Hull, of the sectional committee, and Dr. L. A. Bauer, a member of the general committee.

The officers for the next annual meeting, to be held in Boston during the convocation week of 1909-10 are as follows:

Vice-president and Chairman of Section B—Dr. L. A. Bauer.

Retiring Vice-president—Karl E. Guthe.

Members of the Sectional Committee—K. E. Guthe, L. A. Bauer, A. D. Cole, E. L. Nichols, A. Trowbridge, E. B. Rosa, A. P. Carman, G. F. Hull.

In the afternoon of Tuesday, December 29, Professor Dayton C. Miller delivered an address, as retiring chairman of Section B, on "The Influence of the Material of Wind Instruments on the Tone Quality." This has been published in full in *SCIENCE*, January 29, 1909. It was heard with great interest by a fine audience of about one hundred and fifty. The other seven sessions were attended by from forty to one hundred persons, with an average attendance of about seventy. That on Wednesday forenoon was devoted to subjects of somewhat general interest

and papers by Hayford, More and Bauer of the following program were given at that time.

The hotel headquarters for physicists proved a useful and enjoyable feature of the meetings. Hotel Kernan proved a pleasant gathering place and a large proportion of the visiting physicists were registered here. The most successful social event was the subscription dinner for Section B and the Physical Society, held on Tuesday evening at the Country Club. This was attended by about ninety and was generally declared to be the most successful social gathering of American physicists ever held. The success of the occasion was principally due to the care and zeal of Professor J. S. Ames, of Johns Hopkins University.

The titles and abstracts of the fifty-two papers presented at the several joint sessions are given below.

Fatigue of Metals Excited by Röntgen Rays:

LOUIS T. MORE and R. E. C. GOWDY, University of Cincinnati.

The work is a continuation of the results previously obtained in the same subject and reported at the Chicago meeting of the American Association for the Advancement of Science (see also *Phil. Mag.*, 1907). A new method has been devised for measuring the secondary radiation given off by metals bombarded by X-rays. Previous results have been confirmed and extended.

To account for the secondary radiation, Professor J. J. Thomson has advanced the theory that the X-rays cause a disintegration of the metal and permit the expulsion of charged corpuscles. Our experiments make this theory doubtful. Iron, lead and copper plates with pure surfaces were used and then the plates were coated with thin films of the lower oxides of the metal and again with films of the higher oxides. The effect of this successive oxidation on the fatigue seems to show that chemical changes of the surface produced by the X-rays with the consequent changes of surface-electrified double layers, will account for the phenomena observed.

Errors in Magnetic Testing of Ring Specimens:

M. G. LLOYD, Bureau of Standards, Washington.

This paper is mainly theoretical in character. Formulas are derived connecting the mean magnetizing force with the magnetizing force at the mean radius, and the actual hysteresis loss with the loss which would occur with uniform distribution of flux. Tables and curves illustrate the errors involved and serve to give the necessary corrections in particular cases.

Some Data regarding Recent Magnetic Storms:

L. A. BAUER, Carnegie Institution, Washington.

Renewed interest was recently shown in magnetic storms on account of severe ones last August and September and because of Hale's discovery of the Zeeman magnetic effect in sun-spots. Some concluded that a true explanation of the origin of terrestrial magnetic storms had been found. However, a simple calculation shows that the magnetic field intensity observed in sun-spots is totally inadequate to affect the most sensitive magnetic instruments. Whereas the effects actually observed during storms exceed many times—in fact a hundred fold and more—the limit of measurement (about 1/100,000 C.G.S. unit). Little progress has been made in the solution of the problems presented by magnetic storms, one reason being that the investigations to be thorough are beyond the power of the average individual. They must, hence, generally be restricted either to one particular phase or to one element—usually the change in the compass direction. An important question is that of the seat of the forces regarded as causing the observed effects; whether it be above the earth's surface or below, or even of combined origin. Another fundamental question is, whether an actual change of magnetization in addition to a shift of the magnetic axis takes place, and if so its magnitude and duration. In the case of the very notable storm of October 31–November 1, 1903, it would appear as though an actual diminution of the earth's magnetic moment occurred which continued almost for two months after the apparent cessation of the storm. Similar calculations are in progress regarding the more recent storms.

Optical Properties of Electrolytic Films of Iron, Nickel and Cobalt: C. A. SKINNER and A. Q. TOOL, University of Nebraska.

An Absolute Gauge for Measuring High Hydrostatic Pressures: P. W. BRIDGMAN, Harvard University.

The pressure range over which it has been hitherto possible to measure various physical effects of high pressure has been restricted by the fact that the common forms of pressure gauge leak at very high pressures. The best known work in this field has been that of Amagat, who worked to about 3,000 kgm. per sq. cm. This is the working pressure in modern high power artillery. The essential parts of all gauges for these high pressures are a piston fitting a

cylinder so accurately that the friction between them is small and at the same time the leak past the piston is very slow. At high values of pressure the leak becomes so rapid that it is impossible to make measurements. In this paper a form of the usual gauge was described in which the cylinder is made to shrink automatically by the pressure, so that the leak remains slight even at very high pressures, while the freedom of motion of the piston is not impaired. With this gauge pressure measurements accurate to .1 per cent. have been made to nearly 7,000 kgm. per sq. cm. At higher pressures other parts of the apparatus break. This is not the limit of the gauge.

The Resistance of Mercury as a Secondary Gauge for High Pressures: P. W. BRIDGMAN, Harvard University.

In practical use the above form of gauge is inconvenient because it is slow and unwieldy. In this second paper measurements of the electrical resistance of mercury under pressure are given from which the pressure may be calculated if the change of resistance is known. Electrical resistance is very easy to measure, and it is proposed that in practice pressure be measured in this indirect way. The accuracy attainable is .1 per cent. The total change of resistance for 7,000 kgm. is about 20 per cent. As one would expect, the change in the resistance effected by pressure is less when pressure is high, as is also the change brought about by temperature change. The change of resistance is about ten times the change of volume produced by a corresponding pressure.

Methods for Measuring Compressibilities at High Pressures: P. W. BRIDGMAN, Harvard University.

In this paper methods were described for measuring the cubic compressibility of solids or of liquids at these high pressures. Measurements were made of several samples of steel, glass and aluminum. The values for steel fall between the two best previous determinations, which differ by 100 per cent. The other values agree with the commonly accepted results. The accuracy of the method is about .35 per cent., considerably higher than the best previous determinations. The only liquid measured was mercury. In only one instance has this been measured before to more than 500 kgm., when measurement was made to 3,000 kgm. The value found in this work agrees with former values, except that the change of

compressibility with pressure seems somewhat less than has been supposed.

An Experimental Determination of the Terminal Velocity of Fall of Small Spheres in Air: JOHN ZELENY and L. W. McKEEHAN, University of Minnesota.

Stokes's formula for terminal velocity of fall of a sphere in a viscous fluid expresses the result in terms of the acceleration of gravity, the radius of the sphere, the density of the sphere, the density of the fluid and its viscosity. This formula has been used by J. J. Thomson, H. A. Wilson and others in the determination of the charge carried by a gaseous ion.

The velocity of fall of lycopodium, which satisfies Stokes's criterion that the sphere shall be small, was determined experimentally. Variations in the size and density of individual particles were provided against by finding the time of fall, in a wide tube, of a large number of particles in each experiment. The time of fall of the center of gravity of the cloud of particles was assumed to be that of a single particle of average radius and density. The uniformity of the material makes this admissible.

The formula gives velocities, for this particular size, 50 per cent. in excess of those observed. Since this difference depends probably on the size employed, the amount by which the charge on an ion must be increased can not be stated until further experiments are carried out with particles of different sizes.

Notes on the Effect of the Phase of Harmonics on Sound Waves: M. G. LLOYD and P. G. AGNEW, Bureau of Standards, Washington.

A harmonic alternator set giving frequencies from 60 to 900 was used to excite a telephone. By choosing a fundamental from one machine and a harmonic from another, and then driving the two generators just out of synchronism, a continuous cyclic change of phase relation occurs. Ordinarily the combined tone sounded by the telephone changes periodically, but these changes are really beats due to the interference of higher harmonics common to the two sources. By connecting the generators three phase, star, and choosing frequencies having a ratio of 3 to 1 or 9 to 1, common impurities are eliminated. When so connected no change in the sound could be detected at low intensities. With louder tones there were cyclic changes which were believed to be due to harmonics introduced by the telephone itself, rather than to an actual dependence of quality upon phase.

Magnetic Double Refraction Normal to the Field in Liquids: C. A. SKINNER, University of Nebraska.

Fourteen different liquids were investigated, including nitrobenzol, nitrotoluol, chlor-benzol, brom-benzol, etc. Twelve of them showed electric double refraction. Each was studied through the spectrum from blue to red (440 to 660). The two effects agree in the law of variation. In carbon bisulphide alone were the electric and the magnetic β of opposite sign.

The Absorption Spectra of Various Potassium and Uranyl Salts: HARRY C. JONES and W. W. STRONG, Johns Hopkins University.

The purpose of this investigation was to find out the nature of the absorbers of the light rays and the effects upon them of external conditions. It is possible in the case of the uranium atom or molecule to make a large number of changes that affect its absorbing power. Salts like the nitrate, sulphate, bromide, acetate and chloride of UO_2 have been used. This gives the effect of the chemical radical on the absorption. Different solvents can be used and various concentrations and the temperature varied. The solution can be placed under great pressure or in a powerful magnetic field. Dehydrating agents like aluminium chloride and sulphuric acid can be added. Some or all of these changes are being made and some interesting results have been found.

A Rowland concave grating is used to give the absorption spectra. Wratten and Wainwright red sensitive films are used for the photographic work. The work is being carried on by a grant from the Carnegie Institution of Washington and is a continuation of the work of Jones and Anderson (Publication No. 110, Carnegie Institution).

Beer's law was found to hold for potassium chromate, potassium dichromate, potassium ferrocyanide and potassium ferriyanide. Concentrated solutions of the uranyl salts do not obey Beer's law.

Uranyl salts show ten absorption bands in the blue-green part of the spectrum. When aluminium chloride is added to uranyl chloride these bands are shifted towards the red. Calcium chloride acts in the same way. Several new bands have been found for the chloride (these are very narrow) which none of the other uranyl salts have so far been found to show.

New Series in the Spectra of Ca, Sr and Ba: F. A. SAUNDERS, Syracuse University.

Photographs of the arc and spark spectra of Ca, Sr and Ba, taken with a quartz spectrograph, show several new ultra-violet lines. In Ca a new spectrum series was found, consisting of reversed single lines, beginning with λ 2398, eight lines in all being observed, five of them new. In Sr a similar series exists, seven lines having been observed. In Ba there are evidences of the same sort of thing. Series of *pairs* have been known for some time to exist in these spectra; few of the lines, however, having been picked up. Four new pairs were found in Ba and two in Sr, which help to fill out the two "subordinate" pair series in each of these elements. Formulae which represent these series were calculated out, as was also done in the case of the series first mentioned.

Ionization in Closed Vessels: W. W. STRONG, Johns Hopkins University.

The purpose of these experiments is to find what the nature of the external radiations are, that produce part of the ionization in closed vessels. In order to do this it is necessary to use a vessel in which the ionization produced by the walls of the vessel itself is constant. This ionization can be easily found by putting the vessel within a thick screen of metal or water so that all external radiations are absorbed.

Electroscopes were used for this work and the ionization of the enclosed gas was measured by means of the rate of leak of the electricity from the gold-leaves suspended inside the electroscopes. The charged system inside the electroscope could be charged from the outside by means of a small spark gap. The electroscope was, therefore, airtight and everything inside the vessel remained the same unless affected by radiations that could pass through the walls of the electroscope.

By letting the electroscope into a large cistern it was surrounded by a screen of water at least four feet thick. This was done with an electroscope September, 1907 (*Phys. Rev.*, p. 44, July, 1908). The same electroscope was placed in the same cistern, July, 1908. (Readings of the electroscopes were here given.)

These readings show that the natural ionization within the vessel had remained practically constant throughout almost a year.

The same electroscopes (and others in a like manner) when placed outside of buildings showed very marked increase in its rate of leak during the day. This, therefore, must be due to some external radiation that was screened off by the water in the cistern. (Screens of lead and iron

were also used.) Care was taken to keep the temperature of the electroscope constant.

Velocity of the Negative Ions Produced by the Ultra-violet Rays in Various Gases at Different Pressures and Temperatures: ALOIS F. KOVÁRIK, University of Minnesota.

The object of this investigation is the study of the structure of the negative ion. For this purpose the velocity is measured at different pressures and at different temperatures. The method used is that of an alternating field. In the case of air the product of the velocity by the pressure is nearly constant between the pressures 760 mm. and 200 mm., but at 100 mm. this product increases by 25 per cent., at 80 mm. by 65 per cent. and at 4.3 mm. by 200 per cent. above the value at 760 mm. In the case of CO₂ the product changes a little more rapidly. The velocity of the negative ions in dry air at 760 mm. and 0° C. is 2.05 cm. per second for a gradient of 1 volt per centimeter, and in dry CO₂ at ordinary conditions of pressure and temperature, the velocity is about 1.02 cm. per sec.

Preliminary experiments with change of temperature were made in air and up to 400° C. the velocity was found to vary inversely as the density of air. These experiments are being continued.

Momentum Effects in Electrical Discharge: F. E. NIPHER, Washington University.

An electrical discharge is sent around a right angle in a wire. Spark discharge passes from machine to earth in either the positive or negative line.

A very marked difference between the positive and the negative discharge is found. A decided difference between the effects on the photographic plate is found on the two sides of the angle. The negative discharge is the active one in both lines. An account of these experimental results is given in *SCIENCE* for December 4, 1908. The actual effects were shown by means of a large number of lantern slides.

Electrical Stimulation of Plant Growth: AMON B. PLOWMAN, Beaver, Pa.

Experiments and observations extending through a period of more than ten years, indicate rather conclusively that electrical charges of positive sign more or less completely inhibit the vital processes of plant protoplasm through which such charges are caused to pass; while, within a rather wide range of conditions, negative electrical charges stimulate such processes, sometimes to a quite remarkable degree.

Most of the striking results of electro-culture, including those recently obtained by Sir Oliver Lodge, are quite readily accounted for, if the above conclusions are correct.

This paper was illustrated by means of several photomicrographic and other lantern slides.

Note on the Kathode Equilibrium of the Weston Cell: F. A. WOLFF, Bureau of Standards, Washington.

The Theory of Coupled Circuits: LOUIS COHEN, Bureau of Standards, Washington.

It is a well known phenomenon that when two electrical circuits are coupled together either electromagnetically or direct, two distinct oscillations will be produced in either circuit, and there will also be two distinct damping factors. The problem was the subject of several important papers by several eminent German physicists, but there are certain mathematical difficulties inherent in the problem, which made it difficult to get the complete solution, and all previous investigators limited themselves to some form of approximation.

In this paper an entirely different method of mathematical treatment was adopted and which made it possible to obtain an exact solution. The paper being of a mathematical nature it is rather difficult to give an outline of the work in an abstract. The results are as follows: If we denote by V_1 and V_2 the potentials in the primary and secondary circuits, we have

$$V_1 = \{H_1 e^{-\alpha_1 t} + H_2 e^{-\alpha_2 t}\} \cos \lambda_1 t \\ + \{H_3 e^{-\alpha_1 t} + H_4 e^{-\alpha_2 t}\} \cos \lambda_2 t, \\ V_2 = H_5 \{e^{-\alpha_1 t} + e^{-\alpha_2 t}\} \cos \lambda_1 t \\ + H_6 \{e^{-\alpha_1 t} + e^{-\alpha_2 t}\} \cos \lambda_2 t,$$

α_1 and α_2 are the damping factors, λ_1 and λ_2 are the frequency constants and they have been completely determined.

Photographic Registration of Sounds: DAYTON C. MILLER, Case School of Applied Science, Cleveland.

For making large scale records, showing the details accurately, of complex sound waves having frequencies ranging from 500 to 10,000, the phonograph and oscillograph methods seem unsuitable. The following direct mechanical method has given satisfactory results.

A small steel cylinder, 1 mm. in diameter, is arranged to receive angular motion with a minimum of reaction effects, which is proportional to the displacement of a sensitive diaphragm. A minute mirror, with its plane in the axis of the

cylinder, reflects light to a special camera, and at a distance of 30 cm. gives waves 15 cm. wide which show great detail. Long strips of photographic films were shown and projected by the lantern, showing with great clearness and in full detail the record of overtones, intensity variation, etc., of various spoken phrases. (The words "physical laboratory" received careful and interested attention from the audience.)

The Thermodynamics of Saturated Vapors: J. E. SIEBEL, Chicago, Ill. (Read by title.)

The object of this paper is to demonstrate the necessity of an investigation as to whether certain hypothetical concepts in the theories of thermodynamics and which find their most general expression in the assumption of a universal identical zero of energy (-273° Cels.) and a supposed universally irretrievable dissipation of energy are equally applicable to the thermodynamics of saturated vapors as they appear to be to the thermodynamics of permanent gases.

The Heat Balance in Thermoelectric Batteries: J. E. SIEBEL, Chicago, Ill. (Read by title.)

The author attempts to show that the heat and electricity exchanged in thermoelectric elements are functions of temperature, specific heat and conductivity and produces a formula and calculations made thereby, the results of which latter conform apparently well with a number of experimental results obtained by other observers.

The Effect of the Magnetic Impurities in the Copper Coils of Moving Coil Galvanometers upon their Sensitiveness, Hysteresis and Zero Shift: ANTHONY ZELENY, University of Minnesota.

The magnitude of the effect due to the magnetic impurities in the copper coils upon the sensitiveness of a moving coil galvanometer was determined by obtaining the period of vibration of the coil system in and out of a magnetic field.

If M represents the moment, per unit angle of displacement of the coil, due to the magnetic impurities; T , the torsional moment; and t_1 and t_2 , the periods of vibration of the system when the coil is within and outside of the magnetic field; then

$$M/T = (t_2^2 - t_1^2)/t_1^2.$$

The value of the galvanometer constant is increased due to the magnetic impurities by the factor $(1 + M/T)$.

The values of M/T were determined for several galvanometer coils in fields of various strengths produced by an electromagnet. The values, when using a 1.5 mil phosphor-bronze strip for the upper suspension, varied for different coils from

0.82 to 1.31, in a field whose intensity was 400 units, which is the intensity usually found in ordinary galvanometer fields.

By plotting the relation between M/T and the field strength when the values of the latter were both increasing and decreasing, a marked hysteresis was found, which explain the hysteresis observed in galvanometer deflections whose magnitude depends somewhat on the direction from which the coil comes to its deflected position.

The relation between the strength of the magnetic field and the "set in the fiber" obtained after a reversed deflection was found to be proportional to the strength of the field, except that in weak fields there was no observable set. This shows, as previously explained by the writer, that the set is practically all due to a change in the strength and the direction of magnetization of the impurities in the coil. This magnetization gradually returning to its normal strength and direction explains also, in part at least, the shifting of the zero point with time.

The Three Temperature Coefficients of the Moving Coil Galvanometer and their Relation to the Temperature Coefficients of its Various Parts: ANTHONY ZELENY and O. HOVDA, University of Minnesota.

The values of the temperature coefficients for galvanometers having chilled cast-iron magnets are given in the following table, where B is the temperature coefficient of a particular circuit.

Measurement	Suspension	Coefficient
Current,	{ Phos. bronze,	+ 0.00018
	{ Steel,	+ 0.00005
Potential,	{ Phos. bronze,	+ 0.00018 — B
	{ Steel,	+ 0.00005 — B
Ballistic,	{ Phos. bronze,	— 0.00017
	{ Steel,	— 0.00017

The temperature coefficient for current measurements is shown to be

$$d_k' = F_k + t_k + L_k - D_k, \quad (1)$$

where d_k' , F_k , t_k , L_k , D_k , are the temperature coefficients respectively for deflections, field strength, period of vibration of the coil, and the linear expansion of cast iron and of copper.

The temperature coefficient for potential measurements can be calculated from

$$d_k'' = d_k' - B, \quad (2)$$

where B , as given above, is the temperature coefficient for the resistance of a particular circuit.

The temperature coefficient for ballistic throws is

$$d_k = d_k' - t_k. \quad (3)$$

These equations enable any one of the three temperature coefficients to be calculated from the known temperature coefficients of the various parts of the galvanometer.

The temperature coefficients of a galvanometer with a magnet other than chilled cast iron can be calculated from

$$K' = K + (F_k' + 0.00040), \quad (4)$$

where K represents the value of any particular coefficient given in the above table, corresponding to the one desired, and F_k' is the temperature coefficient of the field strength for the magnet of the galvanometer whose temperature coefficient is to be determined.

A New Method for the Absolute Measurement of Resistance: E. B. ROSA, Bureau of Standards, Washington.

A Plea for Terrestrial and Cosmical Physics: L. A. BAUER, Carnegie Institution, Washington. This paper will be published in full in SCIENCE.

The Ellipticity of the Earth is Not a Proof of a Former Liquid State: JOHN F. HAYFORD, Coast and Geodetic Survey, Washington.

The idea is often expressed, even by physicists of high rank, that the observed ellipticity of the earth is a proof of a former liquid state. This idea is based upon a gross misconception of the magnitude of the stresses which would be produced within the earth by any departure of the actual ellipticity from the value corresponding to the rate of rotation. Sir George Darwin has computed that a departure of only one seventh part, of the actual ellipticity from that corresponding to the rotation, would produce stress-differences in the interior of the earth as great as five tons per square inch. Even the best granite will ordinarily fail under a stress-difference less than five tons per square inch. Therefore, unless the earth in its inner parts is stronger than the best granite it will yield to the stresses and take a new shape before the actual ellipticity has departed from that due to the rotation by as much as one seventh part.

Any one who will start from this as a basis and consider the improbability of the earth being as strong as the best granite throughout, even if it is solid, consider the improbability of the material in the earth being incompressible under stresses applied continuously for ages, and consider the uncertainty introduced into the evaluation of the theoretical ellipticity due to rotation on account of this evaluation being affected by the assumed relation of depth and

density, he will reach the conclusion that the present apparently close agreement between the observed ellipticity and the theoretical ellipticity due to rotation is not a proof of a former liquid state.

He will conclude that it is merely an indication of the strength of the material in the interior of the earth, and that the evidence is far from being sufficient to prove that the strength of the material in the interior, available to resist stress-differences, is now or ever has been so small as to justify the statement that the material is or has been a liquid.

Atomic Theories: L. T. MORE, University of Cincinnati.

*An Electrical Method for Determining the Amount of Moisture in Grain and Other Materials:*¹ ANTHONY ZELENY, University of Minnesota.

Two plates or pointed conductors made of dissimilar metals are inserted into the material in which it is desired to know the amount or percentage of moisture. These plates or points form the electrodes and the moisture the electrolyte of a voltaic battery which causes a current to flow through the galvanometer, whose magnitude depends on the amount of the moisture.

The size of the scale divisions representing any definite amount of moisture is first determined experimentally for each particular kind of material. When the temperature of the material under test influences the magnitude of the deflection, a proper galvanometer shunt is used with its lugs labeled in degrees, so that, when set to indicate the temperature of the material, the proper values for the amount of moisture are obtained regardless of the temperature.

In the case of corn, it was found desirable to have the two dissimilar metals of copper and zinc in the form of points which are pressed into the germ of the individual kernel. The deflection obtained indicates directly the percentage of moisture in the whole kernel. A curve exhibiting the relation between the deflection and the percentage of moisture was shown.

This apparatus is found to be capable of giving values accurate to about 0.1 per cent.

On the Extra Transmission of Electric Waves: F. C. BLAKE, Ohio State University.

With the same apparatus that Blake and Fountain (*Phys. Rev.*, XXIII., p. 257, 1906) used, the conditions insisted upon by Dr. Schaefer (*Phys. Rev.*, XXIV., p. 421, 1907) were fulfilled. Two

¹Patent pending.

diaphragms, 2.5 meters square and of aperture 24 by 32 cm., were inserted, one near the vibrator mirror, the other near the receiver mirror with the resonator system between them. Nine per cent. of *extra transmission* was found, using long strips 3 cm. apart on plate glass. Afterward only a single diaphragm was used, it being placed as near as possible to the receiver mirror. Its aperture was 68.5 cm. long and of a width that was varied from 8 to 61 cm. The *extra transmission* was 15 per cent. in amount and independent of the width of the diaphragm aperture.

Taking this last value as a true measure of the extra transmission it would appear that the use of diaphragms, especially when their apertures are as small as Schaefer demands, introduces errors due to diffraction, but in no case does it completely mask the effect of extra transmission.

Then the vibrator was varied by short steps a distance of 1 cm. either way from its usual focal position of 7.5 cm., a single diaphragm of aperture 68.5 by 16 cm. being used near the receiver mirror. No change in the extra transmission was obtained, although these vibrator changes changed the beam from one quite strongly divergent to a convergent beam.

Entladungsstrahlen: ELIZABETH R. LAIRD, Mount Holyoke College.

A Spectrometer for Electromagnetic Radiation: A. D. COLE, Ohio State University.

The continuation of work on diffraction of electric waves, on which a partial report was given at the New York meeting of the American Association for the Advancement of Science, made it desirable to have a more convenient means of quickly changing the angle between the direction of wave propagation and the line connecting the diffraction edge or slit with the receiver. This resulted in a mounting for the several parts of the apparatus similar to that of the parts of a working spectrometer for light radiation.

It seemed worth while to develop the design still farther, so that the apparatus might later be used by advanced students as a more convenient means of repeating the classical experiments of Hertz, Boltzmann and Righi. The use of the conventional spectrometer design serves to strengthen the force of the analogy between electrical and light radiation, particularly when used for lecture demonstrations, for which it is well adapted. Drawings of the apparatus with a considerable variety of accessories for special uses, were shown and described. By a few simple

changes and adjustments it is easily and quickly adapted for use as an optical bench or as an interferometer for electromagnetic radiation. The wave-lengths preferred are from 10 to 15 cm., the parabolic mirrors of 35 cm. aperture, lenses and prism 22 cm. high, prism-table 26 cm. diameter, and the length over all 225 cm. It is made of oak, and provided with four graduated circles for reading the angles through which different parts of the apparatus are rotated when in use.

A Method of Determining the Electrode Potentials of the Alkali Metals: GILBERT N. LEWIS and CHARLES A. KRAUS, Massachusetts Institute of Technology.

The electrode potentials of the metals of the alkalis and the alkaline earths, notwithstanding their great importance, have never been determined, because of the extreme reactivity of these metals. The method now adopted, which has proved entirely successful in the case of the sodium electrode, consists in measuring the electromotive force between the metal and its dilute amalgam in mercury, with an electrolyte consisting of a solution of a salt of the metal in liquid ethyl amine. The electromotive force so obtained can readily be shown to be independent of the electrolyte and the solvent. It is, therefore, the same as would be obtained if the electromotive force between the metal and amalgam could be measured in an aqueous solution. The potential of the amalgam, against a normal aqueous solution of a salt of the metal may with certain precautions be measured directly against a normal electrode. Adding the electromotive force so obtained to the electromotive force between the metal and amalgam gives directly the potential of the metal in a normal solution of its ion in water (potential of the normal electrode taken as zero). In the case of sodium, this method has made it possible to determine the electrode potential within a few tenths of a millivolt. The value obtained is about half a volt higher than that which has been previously assumed for the sodium electrode.

Non-Newtonian Mechanics and the Principle of Relativity: GILBERT N. LEWIS and RICHARD C. TOLMAN, Massachusetts Institute of Technology.

The laws of non-Newtonian mechanics previously derived by one of the authors from the fundamental conservation laws and from a simple assumption in regard to the nature of light are identical with those which Einstein has obtained from the principle of relativity and the laws of

electro-dynamics. In this paper it is shown that the same equations may be obtained without the aid of the electro-magnetic theory from the principle of relativity and the conservation laws.

On the Influence of Temperature and Transverse Magnetization upon the Resistance of Bismuth and Nickel: F. C. BLAKE, Ohio State University.

The resistance of nickel and bismuth was investigated over a range of temperature from -192° C. to $+183^{\circ}$ C., and for all field-strengths between 0 and 36.6 kilogauss. For measuring temperature flat spirals of fine platinum wire were attached to the mica supports of the bismuth and nickel spirals. The apparatus was that previously used by duBois and Wills (*Verh. d. D. Phys. Ges.*, I., p. 169, 1890).

At liquid air temperatures no such high values of the resistance of bismuth were obtained as had been obtained by Dewar and Fleming and by duBois and Wills. Instead, a maximum of resistance was found between -160° and -180° C. for fields greater than 30 kilogauss. The higher the field the higher the temperature at which this maximum appeared.

If R' is the resistance in the field H at the temperature T , and R_0 the resistance without the field at 0° C., then $R'/R_0 = f(T, H)$. A set of isothermal curves, $R'/R_0 = f(H)$ and another set of isopedal curves, $R'/R_0 = f(T)$ were experimentally determined.

For nickel a set of isothermal curves, $(R' - R)/R_0 = f(H)$, where R is the resistance of the nickel out of the field at temperature T . For all temperatures investigated the fraction $(R' - R)/R_0$ was negative for fields greater than 2,500 gauss, and its value was greater for the higher temperatures. For fields greater than 10 kilogauss it increased with increasing field except at liquid air temperatures; at -190° C. it was a maximum at 8 kilogauss, decreasing slowly for higher fields. For fields less than 2,500 gauss this fraction was positive and it was thought that part or all of this increase in resistance for low fields could be explained by longitudinal magnetization, whose presence could not be wholly avoided.

A New Form of Standard Resistance: EDWARD B. ROSA, Bureau of Standards, Washington.

The new form of resistance standard, which has been developed at the Bureau of Standards during the past two years, differs from the Reichsanstalt form in being smaller and having the resistance coil sealed air tight in a case that is filled with pure oil, insuring protection for the resistance

coil from the effects of atmospheric moisture, reduces the danger of oxidation due to imperfect covering of shellac, and protects the coil from mechanical injury. The resistances when properly prepared and mounted and protected in this manner, remain remarkably constant in value, whereas open coils in oil almost invariably have a higher resistance in summer than in winter, and fluctuate more or less in value from time to time with the weather. As a result of the discovery of the effect of atmospheric humidity on the resistance of standards made at the Bureau of Standards, the National Physical Laboratory of England has sealed its standards, and the German Reichsanstalt is keeping its standards in a chamber at a constant humidity. The use of the new sealed resistances at the Bureau of Standards has increased the accuracy of resistance work appreciably.

A Proposed Modification of the Kirchhoff Method for the Absolute Measurement of Resistance:
FRANK WENNER, Bureau of Standards, Washington.

An Instrument Designed for More Precise Determination of Magnetic Declination at Sea:
WILLIAM J. PETERS, Department Terrestrial Magnetism, Washington.

The cruises of the *Galilee* in the Pacific Ocean, among other results, made very apparent the necessity of more accurate determinations of magnetic declination than could be made with the ordinary instruments of navigation. A collimating instrument has been constructed by Mr. A. Widmer, mechanician of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, which will be used in experimental work on the vessels now being built for a magnetic survey of the ocean areas. Experiments were made on the last cruise of the *Galilee* which assured the practicability of using such an instrument and indicated the possibility of a high order of accuracy.

Many parts of the Ritchie ten-inch liquid compass were used. The card was altered to a four direction collimator by the addition of four concave mirrors with a scale of seven divisions in the focus of each. This alteration increased the original mass by one twentieth part, but decreased the radius of gyration. The period of the collimator arrangement in liquid is now about eleven seconds at Washington. The angle between a collimator axis and a celestial body is measured by a pocket sextant, the scale being viewed through windows in the bowl. The instrument is

not intended for a navigation instrument, but as a step in the attainment of the highest precision in determinations of magnetic elements at sea.

(The paper will be printed in full in the March number of *Terrestrial Magnetism and Atmospheric Electricity*.)

The Electrical Conductivity of the Atmosphere Over the Pacific Ocean: PAUL H. DIKE, Carnegie Institution, Washington.

The work described was done on board the Magnetic Survey Yacht *Galilee* during the cruise of 1907-08. The purpose was to obtain data as to the earth-air current at sea, to compare with similar results obtained on land. The method involves the measurement of two quantities, the specific conductivity of the air and the vertical potential gradient. The latter measurement was found to be impracticable on board ship, and only a few values were obtained, during a calm. These were of the same order of magnitude as are ordinarily observed on land. The specific conductivity of the air was measured by means of the Gerdien apparatus, consisting of a cylindrical condenser, the inner cylinder of which is connected with an electroscope. The conductivity of the air is computed from the rate of dispersion of a charge put upon the inner cylinder when a uniform current of air is drawn through the apparatus. The reading of the electroscope offered the principal difficulty.

The mean values of the conductivity from all the observations of the voyage were as follows:

$$\lambda_p = 1.603 \times 10^{-4} \text{ electrostatic units.}$$

$$\lambda_n = 1.433 \times 10^{-4} \quad " \quad "$$

$$\lambda_p/\lambda_n = 1.12$$

Assuming a potential gradient of 100 volts-meter these values of conductivity give a vertical earth-air current 3×10^{-11} amperes per square centimeter of the earth's surface, slightly larger than the usual value on land. No variation with latitude was discernible, though the observations extended from 05° 41' north to 45° 07' south.

Ultra-violet Absorption and Fluorescence and the Complete Balmer Series of Sodium Vapor: R. W. WOOD, Johns Hopkins University.

The absorption spectrum of dense sodium vapor, contained in a steel tube one meter in length, provided with quartz windows and heated red hot in a combustion furnace, shows the lines of the principal series (Balmer formula) reversed. But seven lines of this series have been previously observed, the observations having been confined to the emission spectrum.

Employing a small quartz spectrograph by Fuess (focus 15 cm.) 24 lines were found and measured and indications of the "head" of the series appeared in the plate though it was not resolved into lines.

With the large quartz spectrograph of the Bureau of Standards 48 lines were resolved, bringing us within 0.1 of an Angstrom unit of the theoretical head of the band. The largest number of lines forming a Balmer series ever observed in the laboratory is twelve in the case of hydrogen (Cornu and Ames). Solar hydrogen (chromosphere) shows 29 lines. The sodium series is 19 ahead of any Balmer series ever observed, even in celestial sources. These ultra-violet lines are accompanied on each side by a channelled spectrum, analogous to the channelled spectra observed in the vicinity of the *D* lines, which form the first member of the Balmer series.

It is in the region of the channelled spectra that the interesting results in the fluorescence of the vapor previously described were found. An attempt was accordingly made to ascertain if the ultra-violet channelled spectra exhibited the same phenomena. Such was found to be the case. Exciting the vapor with the zinc spark, a strong fluorescence was found to be stimulated by the zinc triplet at 3344-3302.

Results of Some Recent Intercomparisons of Magnetic Standards by the Carnegie Institution of Washington; J. A. FLEMING, Carnegie Institution, Washington.

One important detail of the magnetic survey of the globe undertaken by the Department of Terrestrial Magnetism of the Carnegie Institution of Washington is that of the correlation of the observatory standards of various governments and institutions. Comparisons have already been made at seventeen observatories in various parts of the world; the results of the four most recent intercomparisons were discussed in detail in the paper and may be summarized thus: The following corrections should be applied to the provisional standards of the Department of Terrestrial Magnetism of the Carnegie Institution. The probable errors of mean differences are given with them. For Kew Observatory; declination $+0^{\circ}.6 \pm 0^{\circ}.15$, horizontal intensity $-0.0001H \pm .00005H$, inclination $-2^{\circ}.6 \pm 0^{\circ}.1$. For Helwan; dec. $+0^{\circ}.5 \pm 0^{\circ}.1$, hor. intens. $+0.0004H \pm .00004H$, inclin. $+0^{\circ}.1 \pm 0^{\circ}.1$. For Tiflis; dec. $+0^{\circ}.7$, hor. inten. $+0.0008H \pm 0.00006H$, inclin. $-1^{\circ}.7 \pm 0^{\circ}.1$. For Christchurch; dec. $+1^{\circ}.5$

± 0.04 , hor. inten. $+0.0006H \pm .00006H$, inclin. $-1^{\circ}.2 \pm 0.3$.

The values are to be applied algebraically, east declinations, north inclinations and horizontal intensities being considered positive, and west declinations and south inclinations, negative. The preliminary "International Magnetic Standard" for horizontal intensity is confirmed in view of the accordance of the correction at Kew with the indications of Watson's determinations of the earth's field in international units.

A Critical Review of the Problem of Pressure in the Kinetic Theory of Gases: LUIGI D'AURIA, Philadelphia, Pa.

This paper seeks to show that the recognized method of solution of this problem is erroneous and the gaseous pressure per unit area is equal to the energy of agitation of the gas per unit volume. It will be printed in *Popular Astronomy*.

The Dynamophone: J. BURKETT WEBB, Stevens Institute of Technology.

Some years ago the problem arose of measuring the power which a turbine transmitted through its shaft to the propeller. The ordinary "indicator" being useless, a method depending on the torsion of the shaft was invented. As it was the intention to protect it by patent, it could not be published sooner, but it has leaked out somewhat and more or less incorrect references to it have appeared in German papers.

The first idea was to measure the torque optically, but a better method was adopted. The apparatus necessitates no mechanical contact with the shaft and the speed can also be observed without the usual speed counter. The degree of accuracy is very high, there being no difficulty in making single observations within one per cent. of error.

The apparatus consists of two toothed iron rings which are fixed permanently to the flanges of the shaft at as great a distance apart as possible. Opposite these rings on a frame fast to the floor are mounted telephone magnets adjustable radially and concentrically as to the shaft axis. Each ring and magnet (or pair of magnets) constitutes an alternating dynamo whose current intensity can be regulated by the radial adjustment of its magnet and whose phase can be varied by the concentric movement, and these two dynamos are connected in series so that when the shaft is not twisted their phases are opposite and neutralize each other in a receiver inserted in the circuit. When, however, the shaft twists the phases become different and a clear tone is perceived.

To measure the torque one of the concentric adjustments is then made until the tone disappears and the angular change read on a scale graduated preferably to horsepower per revolution. The pitch of the tone compared with a calibrated tuning fork gives the speed. The necessary calibration of the shaft is made before it is placed in position or it can be made afterward. (A model was shown.)

Some Optical Effects of Changes in Ether Density: CHARLES F. BRUSH, Cleveland, Ohio. (Read by title.)

The Lumeter, a Practical Measure of General Luminosity: HENRY E. WETHERILL, M.D., Philadelphia. (Read by title.)

A Ballistic Dynamometer Method of Measuring Hysteresis Loss in Iron: MARTIN E. RICE and BURTON McCOLLUM, University of Kansas. (Read by title.)

The sample to be tested, which should be laminated, is wound with a primary coil and a test coil. The latter is connected in series with the fine wire movable coil of a dynamometer and the former in a series with the coarse wire-fixed coil of the dynamometer. When the primary current is reversed, the dynamometer measures by its ballistic deflection the total energy loss per half cycle in the iron and in the test coil circuit. Since the hysteresis loss is independent of the period of the cycle while all the other losses measured are inversely proportional to the period of the cycle, it is easily possible by the insertion of a choke coil in the primary circuit and the use of a moderately high resistance test coil circuit to keep these other losses below one per cent. of the total loss measured. A comparatively rough estimate of these other losses is then sufficient to enable the true hysteresis loss to be determined with an error of only a small fraction of one per cent.

The dynamometer can be calibrated by discharging a condenser or a mutual inductance through its movable coil while a constant current is maintained in its fixed coil.

This method eliminates the difficulties inherent in the wattmeter methods due to uncertainties in frequency and wave shape while it avoids the tedious process of taking a long series of readings, plotting a curve and measuring its area, as in the ballistic galvanometer methods. Tests can be made much more rapidly than by the wattmeter methods, while the results obtained are fully as accurate as by the ballistic galvanometer methods.

On the Diurnal Variations in the Intensity of the Penetrating Radiation Present at the Surface of the Earth: G. A. CLINE, Toronto University.

On the Character of the Radiation from Potassium: J. C. McLENNAN, Toronto University.

The Action of Electrolytes on Copper Colloidal Solution: E. F. BURTON, Toronto University.

The experiments detailed in the present communication are a continuation of those performed by the writer on the action of small traces of electrolytes on silver and gold colloidal solutions prepared by Bredig's method. With these solutions the particles in the pure solution are negatively charged and it was found that, if an electrolyte was added, the positively charged ion was the potent one in reducing the velocity with which the particle moved in a given electric field; *i. e.*, the ion charged oppositely to the colloidal particle produces the discharge of the particle and consequently coagulation of the colloid.

Copper colloidal solutions were chosen on which to work because they have positively charged particles in the pure solution. The electrolytes used were solutions of potassium chloride, potassium sulphate, aluminium sulphate, potassium phosphate, potassium ferricyanide. With this series it was possible to compare the effect of the monovalent and the trivalent ions of both acids and bases.

Every electrolyte added produced a decrease of the velocity with which the copper particles moved to the cathode. It is the ion bearing the negative charge which is active in reducing the velocity. This power of the negative ion depends on the valency in a way analogous to the relations found by Picton and Linder, and Hardy for the coagulative power of ions. Evidence is also produced to show that the discharging power of two negative ions of the same valency is the same. Current observations on the coagulation of the colloids in each case showed that the particles coagulate more and more freely as the charge gets smaller and smaller.

Arc and Spark Phenomena in the Secondary of a High Potential Transformer: E. S. JOHANNOTT, Rose Polytechnic Institute. (Read by title.)

The Upper Inversion in the Atmosphere: W. J. HUMPHREYS, Mt. Weather Observatory, Md.

We have been accustomed to think of the atmosphere as growing steadily colder to nearly or quite absolute zero with increase in elevation, but hundreds of records obtained in many parts of the world by the aid of free balloons show that this assumption is very wide of the truth.

These records tell us, among other things:

(a) That through the first ten thousand feet next the earth the temperature changes irregularly, and often has one or more layers warmer than the regions immediately below or above them.

(b) That roughly between ten thousand and forty thousand feet above the surface of the earth the temperature falls tolerably regularly, approximately at the rate of $0^{\circ}.7$ C. per hundred meters, or $0^{\circ}.4$ F. per hundred feet.

(c) That somewhere in the neighborhood of forty thousand feet elevation the temperature quits falling, usually abruptly, and commonly increases slowly from this level up to the greatest elevation yet reached, about 26.6 kilometers (16½ miles).

The place where the temperature quits falling and begins to rise is called the inversion level. Its elevation and its temperature both change with seasons, with latitude, and with storm conditions.

This inversion and all the other phenomena connected with the temperature gradients of the atmosphere appear to be satisfactorily accounted for by the known composition of the atmosphere and the laws of radiation and absorption.

The paper in full appears in the *Astrophysical Journal*, January, 1909.

Some Results in Solar Magnetism: W. J. HUMPHREYS, Mt. Weather Observatory, Md.

The splendid work of Hale and others at Mount Wilson has led to the conclusions: (a) that sun spots are cooler than the surrounding regions; (b) that they are centers of violent cyclones; (c) that they are accompanied by magnetic fields of great intensity.

Assuming the effective temperature of the sun to be $6,000^{\circ}$ C., simple convection can reduce the temperature of solar vapor to about $5,000^{\circ}$ C., so that lower temperatures, if such exist, must be due to some such explosive action as Fox has shown to accompany the spots.

The observed tangential velocity of 100 kilometers per second can not be accounted for as the result of simple differences in barometric gradients.

The observed magnetic field can not be due to a whirling surface charge, since a charge sufficient to produce it would cause disruptive radial forces. A volume charge, however, of the negative sign, analogous to that which somehow exists in the earth's atmosphere might lead to the observed effects.

The magnetic fields of the sun spots, however produced, can not extend in measurable amounts to the earth, and therefore our magnetic storms are still without a definitely assignable cause.

The full paper appears in *Terrestrial Magnetism and Atmospheric Electricity*, December, 1908.

Note on Thermoluminescence: ELIZABETH R. LAIRD, Mt. Holyoke College.

Theory suggests that the change producing luminescence goes on very slowly at ordinary temperatures in thermoluminescent salts and is merely accelerated by raising the temperature. An additive method of obtaining the effect of thermoluminescence should therefore show its existence at room temperatures.

This was tested by wrapping up photographic plates for different periods of time with sensitive film toward a thermoluminescent salt and developing later, at the same time heating the salt to observe the remaining effect.

The salts used were solid salt solution of calcium sulphate and magnesium sulphate, the same with an undetermined admixture and calcium sulphide which had been kept in the dark some time after all visible luminescence had ceased.

The results showed that the photographic plate was unaffected in each case, with exposures varying from two weeks to two months, according to the salt used and the amount of its previous exposure to light. Where the effect was uneven the greater effect corresponded to the portions showing brighter thermoluminescence. Control plates used with salt that had not been exposed to light after heating showed no effect in the same time.

These experiments indicate that there is a slow change in thermoluminescent salts, probably similar to that occurring at a higher temperature.

ALFRED D. COLE,
Secretary

THE AMERICAN PHYSIOLOGICAL SOCIETY

The American Physiological Society met in the physiological laboratory of the Johns Hopkins University, December 28 to 31. Sessions for the reading of papers were held in the forenoons of December 29, 30, 31 and the afternoon of December 31. Demonstrations were given in the afternoon. Seventy papers and demonstrations were presented.

A joint session with the American Society of Biological Chemists was held December 29. On the afternoon of the twenty-ninth the society met with Section K to hear the address of the retiring

vice-president (Dr. L. Hektoen) and for a symposium upon the subject of "The Regulation of Physical Instruction in Schools and Colleges from the Standpoint of Hygiene." On the afternoon of the thirtieth there was a combined meeting with Section K, the Society of American Bacteriologists and the American Society of Biochemists. The following general papers were read and discussed:

"Anaphylaxis," by M. J. Rosenau.

"The Physiological Significance of Creatin and Creatinin," by L. B. Mendel.

"The Cause and Diagnostic Value of the Venous Pulse," by A. W. Hewlett.

The meeting was the largest in the history of the society, more than 80 members being present.

The following were elected to membership: T. G. Brodie, of Toronto; W. W. Hale, of Washington; W. A. Hewlett, of Ann Arbor; A. D. Hirschfelder, of Baltimore; A. Hunter, of Ithaca, N. Y.; D. R. Joseph, of New York; W. J. Meek, of Madison, Wis.; F. R. Miller, of Toronto; F. H. Scott, of Minneapolis; S. Simpson, of Ithaca; C. Voegtlin, of Baltimore.

The following officers were elected:

President—W. H. Howell.

Secretary—R. Hunt.

Treasurer—W. B. Cannon.

Additional Members of Council—A. J. Carlsen, W. P. Lombard.

REID HUNT,
Secretary

THE AMERICAN ASSOCIATION OF ECONOMIC ENTOMOLOGISTS

THE twenty-first annual meeting of the American Association of Economic Entomologists was held at the Eastern Female High School, Baltimore, Md., December 28 and 29, 1908. The annual address of the president was presented by Dr. S. A. Forbes, on "Aspects of Progress in Economic Entomology." A full program of interesting papers was presented at each session. A general discussion of the subject "Do we Need the Insectary?" was participated in by many of the members and many important facts were brought out in connection with the use of this important accessory to entomological work.

The report of the secretary showed that the association was making a healthy growth and that it was in a good financial condition.

A considerable amount of important business was transacted at the meeting which included a revision of the constitution, the adoption of a resolution defining the attitude of the association

concerning the proposed affiliation of societies interested in agricultural science and the adoption of memorial resolutions on the deaths of Dr. William H. Ashmead, Alexander Craw, Dr. James Fletcher, Professor W. G. Johnson and Professor F. H. Snow, members who had died during the past year.

A long list of uniform common names of insects were adopted on recommendation of the committee on nomenclature.

Thirty-nine new members were elected.

The following officers were elected:

President—Dr. W. E. Britton, New Haven, Conn.

First Vice-president—Dr. E. D. Ball, Logan, Utah.

Second Vice-president—Professor H. E. Sumners, Ames, Iowa.

Secretary—Mr. A. F. Burgess, Washington, D. C.

Member of the Committee on Nomenclature—Professor Herbert Osborn, Columbus, Ohio.

Members of the Advisory Board of the Journal of Economic Entomology—Professor Wilmon Newell, Baton Rouge, La., Dr. H. T. Fernald, Amherst, Mass., and Professor Herbert Osborn, Columbus, Ohio.

Members of the Council of the American Association for the Advancement of Science—Dr. S. A. Forbes, Urbana, Ill., and Professor H. E. Sumners, Ames, Iowa.

The attendance was the largest of any meeting in the history of the association, over a hundred being present at every session.

A. F. BURGESS,
Secretary

SOCIETIES AND ACADEMIES

THE NEW YORK ACADEMY OF SCIENCES SECTION OF BIOLOGY

THE regular meeting of the section held at the American Museum on January 11, 1909, was devoted to an illustrated lecture by Professor E. B. Poulton, of Oxford University, on "Mimicry among North American Butterflies." The lecturer was introduced by Mr. Charles F. Cox, president of the New York Academy, who made some brief remarks on selection and mimicry.

Prior to the scientific program a letter was read from Mr. W. K. Gregory, regretfully declining the election to the secretaryship of the section for 1909. Dr. L. Hussakof was then nominated and elected to the office for the same term.

A REGULAR meeting of the section was held at the American Museum, on February 8, 1909, Mr. Frank M. Chapman, chairman of the section, presiding. The following papers were read:

A New Example of Determinate Evolution: Professor BASHFORD DEAN.

In a previous paper the speaker had shown that the egg-capsule of the chimeroids at the time of deposition is adapted with singular precision to the needs of the future embryo, and had given reasons for the view that this adaptation was orthogenetic rather than selectional, in a legitimate sense. It was now shown that the egg-capsules of various chimeroids could be arranged in an orthogenetic series. In this series the head-and-body portion of the capsule becomes progressively shorter, the tail portion more slender, the lateral web disappears, the opening valve increases in length, the serrulae of this valve reduce to a smaller area, and the respiratory pores of the tail end of the capsule to a longer one. This progressive series is accentuated by the recent discovery of an undetermined capsule from the North Atlantic (*C. (Bathyalopex) mirabilis*) received by the speaker from Professor Jungersen, of Copenhagen.

Some Interesting Reptiles: Mr. RAYMOND L. DIMMERS.

The speaker exhibited a series of living lizards and serpents illustrating the salient features in the evolution and classification of these groups.

The serpents are undoubtedly derived from lizards. Some of the latter possess grooved teeth and a series may be arranged among them showing the progressive decline in morphological and functional importance of the limbs. This series begins with such a form as the dragon lizard (*Basiliscus*) with long hind limbs and which, in running, carries its body clear above ground. In other forms the limbs are not so well developed, so that the body rests entirely on the ground (*Heloderma*) or may even be dragged (*Oxybelodon*). A connecting link between serpents and lizards was exhibited (*Ophisaurus*). This form looks exactly like a snake, but is a true lizard.

In the serpents there are no traces of external limbs, though with the boas and pythons internal ones are present. The jaw is greatly distensible, and true grooved or canaliculated fangs are developed among many. A number of interesting points in the habits of the serpents were brought out.

Field Observations on the Fin Whales of the North Pacific: Mr. ROY C. ANDREWS.

Mr. Andrews gave an account, illustrated by lantern slides, of his experiences while at the whaling stations on the coast of Vancouver Island and southern Alaska. The paper was devoted to a discussion of the habits of some members of the family Balænopteridæ and of the modern methods employed in their capture. Many reproductions of photographs were shown on the screen illustrating the manner of spouting, diving and feeding of these whales. The speaker dwelt especially upon the peculiar manner in which the nasal region is protruded during respiration, and upon the attitudes assumed by the animals when diving. The method of feeding and the movements during play were also discussed.

L. HUSSAKOFF,
Secretary

AMERICAN MUSEUM OF NATURAL HISTORY

THE ANTHROPOLOGICAL SOCIETY OF WASHINGTON

At the 429th regular meeting of the society, February 16, 1909, Mr. Robert Grosvener Valentine, the Assistant Commissioner of Indian Affairs, delivered an address on "The Unspoiled Indian," illustrating his remarks by the specific instance of the San Carlos Apache. The speaker said that the Indian had suffered less on account of that of which he had been despoiled than from the benefits which had been unwisely conferred upon him. He declared that he must be educated through his home, and therefore it is better to locate schools in Indian neighborhoods rather than remove the Indians from their homes and educate them apart as was the older government policy. In opening lands next to Indian reservations for settlement he believed it was important that the right kind of white men be induced to locate there. He favored opening such lands block by block to companies of settlers who had previously been neighbors rather than the present plan of throwing open all at once and bringing on a spectacular rush from all quarters.

The address provoked a lively discussion participated in by Dr. Merriam, Dr. McGee, Dr. Hough and the speaker, after which the president exhibited some blankets, belts and other articles made by the Apache and Navaho, and Dr. Merriam showed several pendants worked by California Indians out of feathers of the red flicker.

THE REGULATION OF PHYSICAL INSTRUCTION IN SCHOOLS AND COLLEGES FROM THE STANDPOINT OF HYGIENE¹

THE researches of modern physiologists on the growth of the brain and nervous system have done more to place the physical instruction of the young on a sound and logical basis than any other influence that can be named, for the specialization of the child's muscular system progresses with the increasing complexity of the brain, and the evolution of his physical nature is but an epitome of the evolution of the whole race.

The infant is born with but two definite voluntary movements, sucking and grasping, necessary for self preservation; all others consist of aimless waving and kicking of the arms and legs and it is not until the assumption of the upright position that the specialization begins that advances him above his four-footed fellows.

Relieved of their function of support, the arms rapidly learn movements of throwing and striking, grasping and pulling, and he familiarizes himself quickly with his surroundings and soon begins the imitation of the movements in animals and people and machines that are within his range of observation.

¹ An address delivered in a symposium on "The Regulation of Physical Instruction in Schools and Colleges, from the Standpoint of Hygiene" before Section K (Physiology and Experimental Medicine) of the American Association for the Advancement of Science, Baltimore, December 20, 1908.

This goes on with increasing freedom. He learns to handle hammers; to cut with a knife; to throw and catch and strike; to explore and hunt; to run and climb.

At the age of twelve the second great change takes place in his evolution. He finds that he is part of a community and begins to take interest in games involving organization. He becomes one of a gang or team, and this involves cooperation, self-sacrifice and discipline—qualities that he does not recognize before this stage.

A band of savages who have organized to fight under a chief instead of every man by his own hand have arrived at the same stage of evolution as Anglo-Saxon boys of twelve to fourteen, as has been so well pointed out by Gulick.

A rational system of physical instruction must follow this evolution if it is to be hygienic or successful, and this was done with preeminent success by Froebel in the kindergarten, where the games and exercises are designed to imitate the hopping of birds, the flying of bees, the circling arms of the wind-mill—objects familiar to the child and appealing to his awakening imagination.

With his increasing age the child is promoted to the lower grades of the public school where space becomes valuable and his freedom is curtailed by the limitations of the school room. The normal occupation of a child is play, but school life means periods of fixed posture and the first application of the hand of discipline to prepare him for community life.

Corrective exercises to overcome the evil tendencies of prolonged sitting when writing and reading must now be introduced, and the time for free play is curtailed.

The well-rounded course would contain these corrective exercises given at frequent intervals throughout the day; class exercises and marching for discipline; and the

plays and games that children of that age have always played, modified in some cases to fit the limitations of time and space imposed by the school hours and the play ground.

At about sixteen there is a break in the youth's education. Most children finish their formal studies and go into their life's work. A few go on to college; but the freshman class of a college is also made up of young men recruited from the farm, the shop, the office, the factory and the night school, presenting all the mental and moral defects of these widely varying occupations. Many of them have uncorrected eye defects; round or crooked backs; narrow, flat chests and flabby muscles. The play instinct may have been crushed out by the hard grinding life of the factory, or office, and they may have lost the knowledge and desire to play. They are old before their time. In contrast to those are the undisciplined and self-sufficient athletic men, who do not take kindly to the discipline of college life, considering it as an unnecessary evil to be avoided as much as possible.

A careful physical examination should precede any attempt to provide physical instruction for college students.

This examination should include data on family history; habits of life; health history, obtained by leading questions which may be followed up if necessary; tests of simple maximum effort in the movements most frequently employed, extension of the back and legs, flexion and extension of the arms, the grasping power and lung capacity, with a certain number of measurements for purposes of comparison.

The students may then be divided into three classes: (1) Defective, (2) average and (3) athletes.

Defectives need personal advice and individual prescription to correct flat foot, uneven shoulders, constipation, hernia,

obesity, old heart lesions or joint injuries. These are given on cards and the student taken over each exercise in detail by an instructor who reports at frequent intervals.

The average man may be taken in classes which should begin by exercises of discipline, marching and setting-up movements to word of command. They should then be examined to find their ability to perform certain exercises of skill, and classified according to their proficiency. A course of graded exercises should follow, closing with a re-examination. This procedure may be repeated three or four times during the college year.

In designing the exercise to be given to the college student, the evolution of the race must be kept in mind and the old co-ordinations that have been responsible for its development must be used as much as possible in a natural manner.

1. *Locomotion*: in marching, running, jumping, dancing, tumbling, climbing and swimming.

2. Throwing large and small balls for distance and accuracy. Catching and dodging.

3. *Fighting*: by striking, as in boxing; by grappling, as in wrestling; by thrusting, as in fencing; and by striking, as in single stick or saber.

Some of these are best taught indoors, but where it is possible all exercises should be taken in the open air.

All the most popular athletic contests can be arranged to apply to the general mass of the students by setting a low standard, by having the whole class try a feat at once, by doing the exercise to word of command, and by stopping short of great fatigue.

After a certain time there is a tendency to specialize in those who find the general class work too easy, and this may be found on entrance to college in some whose pre-

liminary training has been obtained in preparatory schools. They naturally drift into competitive athletics, but this involves an entirely different kind of training from that already described.

The distinction between physical training and athletic training must be sharply defined.

In physical training the object is to bring the standard of health up to its highest level, and all excessive strain or exhaustion is avoided while all the activities are exercised.

In athletic training the object is to bring the human machine to its highest point of efficiency to perform a definite feat, and everything that is useless or detrimental is sacrificed. The heart is made larger and stronger than is necessary for ordinary life if the feat to be performed is one of endurance. The nervous system is made irritable and alert if speed is required, the special muscles are developed, and the normal store of fat is lessened if agility is the necessary requirement. The object is not primarily health but superlative ability, either in strength, speed or endurance, and the undue absorption of fat leaves the constitution less able to withstand the siege of a constitutional infection like typhoid fever or pneumonia in which a moderate amount of fat is a valuable asset.

In deciding the value or harmfulness of athletic training, however, the physiologist has not always the last word to say. The ethical and social sides assume here an importance that overshadows the purely physiological consideration. The athletic class will never exceed ten or fifteen per cent. of a college community, and it is after all for the main body of students whose interests are not primarily athletic that physical instruction must be considered and its details planned so that they may be enabled to graduate stronger,

sounder, more self-reliant and more efficient.

R. TAIT MCKENZIE

UNIVERSITY OF PENNSYLVANIA

ON THE PHYSIOLOGICAL EFFECTS OF
MODERATE MUSCULAR ACTIVITY
AND OF STRAIN¹

PRACTICAL efforts, both in Europe and America, to solve the problem of physical training in schools and colleges have proceeded along two different lines, which are roughly typified in Europe by the English system, on the one hand, and the Swedish and German systems, on the other. In the former, athletic efforts may be said to play a predominant rôle; in the latter, they are strictly subordinated in the endeavor to reach the masses. Similarly, the practise in America differs considerably. In some colleges the great stress is laid upon athletics; in others athletic activities are entirely separate from instruction in physical training for the student body as a whole. But these are the extremes, for in the majority of cases the organization of the work combines, or seeks to combine, both. Perhaps it will be conducive to clearer thinking if we define at the outset the difference between the two extremes.

In those cases where athletics are under separate organization and control, it is the aim of the department of physical training to secure for each individual student the proper basis of health for his work in school or college and also to educate him in the truest sense of that word for the proper hygienic conduct of his subsequent life. Physical training is not regarded as an end in itself, but as an essential means

toward the equipment of the individual for the work in which he may engage. The effort is, furthermore, made to do this economically as regards both time and effort.

The athletic ideal is entirely different. It does constitute at the time an end in itself; its primary purpose is not the cultivation of health, but of excelling some one else. It brings into play the elements of competition and championship. The athletic team of a school or college represents the best which the institution can do in that line of effort. Sacrifices of time, of convenience, and, generally, to some extent at least, of scholarship, are regarded as proper, if needed to secure the immediate end in view. Physical risks must be taken if necessary, risks which may end in permanent injury, and even in death, in order that one's college shall prove itself superior to some other college.

There are thus, these two ideals which come into practical work of physical training. It is of course not necessary that we adopt one to the exclusion of the other; but these ideals profoundly influence the practical measures adopted, and it is essential that we approach the solution of our problem from the right point of view. It should be added that, in giving each its due weight, other considerations than the strictly hygienic must enter into our decision. First, there is the question whether a given plan of action reaches the masses and is effective with them from the standpoint of physical training; and there is also the question whether we do not need to cultivate those moral qualities of group loyalty, of subordination of self to the interest of the whole, and of the willingness to make the supreme effort for a common cause, which is perhaps the very soul of modern school and college athletics. These are questions on which obviously the physiologist has not the last word,

¹ An address delivered in a symposium on "The Regulation of Physical Instruction in Schools and Colleges, from the Standpoint of Hygiene" before Section K (Physiology and Experimental Medicine) of the American Association for the Advancement of Science, Baltimore, December 20, 1908.

although he must have an important share in their answer.

Returning to the strictly hygienic side of the question, I am simply trying to get clear in your minds the fact that there are these two ideals and that one of them involves the necessity of training for and, at times, the making of a supreme physical effort on the part of the contestant. The other does not involve this element; on the contrary, perhaps it generally seeks to avoid it, thus leaving the individual free to concentrate his effort on some other object.

Now, whether we attempt or do not attempt to include these elements of moral education in our efforts at physical training, it is of first importance that we secure the hygienic ends and that our work be successful with the masses and not solely with those who finally engage in athletic contests. Not only this, but, viewing physical training as a part of education as a whole, it is even fair to demand of it that it do more than provide the physical capital for the work of life by securing the proper development of the body during the period of youth; it should also lay the foundation of correct habits; it should leave the student with the ability to enjoy those forms of physical activity which are possible amid the more serious concerns of adult life, and with a compelling belief in the necessity, even the obligation, of maintaining the physical man.

With this in mind, let us review rapidly the biological requirements of the human body for muscular activity as an essential factor in health. In this audience, it would be only to state a truism to say that the human frame is constructed for a life of muscular activity; that the fact that, until very recently, mankind has supported itself by physical rather than by mental exertion must have led to the sur-

vival of those with bodies adapted to physical exertion. So essential was it that this adaptation should be of a very high order, that we are not surprised to find that it went to the extent of producing a body not only capable of sustaining, but even of profiting by, physical exertion.

Assuming that this adaptation of the organism for muscular activity is the result of a hard process of natural selection, we should expect to find that the extent of the adaptation is determined by its survival value; that is to say, it would not be reasonable to expect adaptation of the race as a whole to degrees or forms of muscular exertion which formed no part of the daily life of the average man or woman, and we may assume to-day that the race as a whole is not likely to profit by forms of activity distinctly more strenuous than those to which it has been accustomed in the past.

"The muscular activity which thus formed part of the life of our ancestors may be described as generally moderate, though at times it was vigorous or hard; only exceptionally did it involve extreme endurance or great muscular strain. . . . Where work of this kind had to be done it was left to those who, by reason of exceptional strength, were especially fitted for it." It would seem that it is to such work that the race, as a whole, is adapted and there is thus a strong *a priori* theoretical probability that it is by such work that it is most benefited. In using the term "moderate muscular activity" in this discussion, you will understand that I am referring to work of this kind. And it is sufficiently obvious that the training for beating a record, or for rowing, or football is something distinctly in excess of this.

Through what physiological channels

*Hough and Sedgwick, "The Human Mechanism," p. 312.

does this moderate muscular activity minister to the health of the body? We can not discuss this at any length here, and to do so would only be to repeat what has been explained over and over again. But we may mention the following as the principal hygienic effects.

1. Muscular activity affords training to the heart, so that it is not only equal to the emergencies of life, but is also able to withstand the fatigue of moderate prolonged exertion. No exercise can be enjoyed unless this fundamental condition is satisfied.

2. Muscular activity relieves vascular congestions in the internal organs by bringing larger quantities of blood to the skin. In doing this it improves the physiological condition of the skin, as well as that of deeper organs.

3. As a result of the deepened and frequently quickened respiration all lobes of the lungs are used and the apical lobes rendered less liable to the attacks of disease.

4. As a further result of the increased breathing movements, as well as of the pumping action of contracting muscles and movements at joints, the flow of lymph along the lymphatics is greatly favored, and this improves the environmental condition of all cells of the body.

5. Muscular activity also affords important training to the heat-regulating mechanism of the body.

6. Muscular activity exerts a favorable influence upon the digestive processes, promoting proper secretion and absorption and tending to prevent the unhealthful conditions leading to constipation.

7. Muscular activity is conducive to refreshing slumber. This is partly because of the maintenance of normal conditions in the body generally and probably, in part, because it is conducive to the healthful fatigue which facilitates the normal

relaxation from nervous strain. Whatever may be the physiological explanation of the phenomenon, there can be no question of its existence and of its hygienic value to the nervous system.

It is not essential to our purpose that we make a complete list of these favorable physiological effects. Probably the above comprises the more important of them, and before leaving this part of our subject we may point out two things. First: these are all hygienic essentials and most, if not all, of them can be properly secured only by muscular activity. The training of the heart, the maintenance of deepened breathing without depriving the blood of its due charge of carbon dioxide, the favorable effect on the flow of lymph—for it is an old physiological observation that there is no lymph flow from the limbs when motionless—the favorable effects on digestive functions and on slumber, all of these can be secured in *no other way* than by muscular activity. This means that physical training is an essential in any properly planned course of education and that no school or college is justified on any ground whatsoever in failing to provide properly for this need of its students. Second: all these hygienic effects can be secured by what we have termed “moderate” exercise. Not one of them requires the effort involved in training for athletic events. This fact seems to me to justify a statement which I have made elsewhere to the effect that “the athletic ideal is not the hygienic ideal; it may not be unhygienic, but it is not required for purposes of health.”

But athletic training and athletic contests may be at least desirable and possibly necessary for other than hygienic purposes; and so the question at once presents itself whether in using it for these purposes unjustifiable risks to health are

taken. What are the physiological effects of the training for and the participation in such efforts?

The contribution of the physiologist to the answer to this question must be limited to a statement of what is known of the physiological conditions during strain. It is for the clinician to tell us how far these dangers actually produce ill effects; and the clinical evidence, to be at all satisfactory, must be drawn, not simply from the study of cases which apply for treatment, but from a systematic study of an entire group of *average* people participating in such work. For it must be remembered that the appeal of athletics is not simply to those who will finally make a school or college team, but to a much larger proportion of the student body.

First, I think we should make sure that we appreciate the weight of the burden of physiological adjustment which muscular activity places upon the organism, for this is always greater than is generally supposed. It may be measured with a fair degree of accuracy by the respiratory exchange, since this varies almost *pari passu* with the work. The comparison must, however, be made between the expired air, collected directly from the respiratory passages, during rest and during the actual performance of work. Measurements made in respiration chambers, unless the work extends over several hours (and very severe work can not be maintained continuously for this length of time), necessarily involve some lag in the collection of the samples. I will quote from two reliable observations involving such direct analyses of the expired air.

Leo Zuntz² found that the oxygen consumed per minute while riding a bicycle on a level asphalt track at a speed of nine miles an hour increased from 263 c.cm.

²Leo Zuntz, "Untersuchungen über den Gasaustausch und Energieumsatz des Radfahrers."

(during rest) to 1,550 c.cm., and that when the speed was increased to thirteen miles an hour it rose to 2,058 c.cm., an increase of eightfold. This corresponds very closely with what Zuntz and Lehmann⁴ had previously found for the horse, where the oxygen consumed and the carbon dioxide excreted per minute increased from five to ten fold with moderately heavy to hard work, respectively. All observations, moreover, show that this respiratory need must be met at once, which means an enormous increase of work on the part of the respiratory and vascular systems. When we find the muscular work of the sitting posture almost doubling that of the sleeping condition; even light activity doubling the work of the sitting posture; only moderately heavy work increasing it four or five fold, while vigorous activity increases it eight and ten fold; and when we reflect that all this must be immediately provided for in the successful readjustment of the circulation and respiration—we begin to appreciate the possibilities of physical strain.

Two very different forms of muscular activity introduce into the organism conditions of strain and the nature of the strain in the two cases is very different; first, when a supreme effort is put forth suddenly and for comparatively brief periods of time, as in the hundred yards' dash; and, second, where vigorous but less violent exertion is prolonged over a much greater time, as in long-distance running. Probably the chief dangers in the two cases are, respectively, excessive arterial pressure, at times combined with disturbance of the pumping action of the heart, and fatigue.

With regard to arterial pressure during muscular activity, the reliable data at hand are sufficient to give us an idea of

⁴Zuntz and Lehmann, "Stoffwechsel des Pferdes," Berlin, 1889.

the possible strain which may at times be placed upon the heart and arteries, but they do not give us the knowledge we should have of the pressure conditions during fatigue. It is clear enough that in the increased output from the heart and the probable constriction of the arterioles of the splanchnic and other internal organs pressor factors are introduced, while in the dilation of muscular and cutaneous arterioles depressor factors are introduced; through the changes of thoracic aspiration and the rhythmic pressures on the bloodvessels of the working muscle and moving joints, arterial pressure must also be influenced, the exact direction of the influence probably differing with the nature of the exercise and the condition of the organism. Finally, where very rapid rhythmic or sustained contractions are made, the blocking of the circulation through the muscles must exert a marked depressor influence. The net result must be the algebraic sum of these pressor and depressor influences and we are prepared to find, as we actually do, considerable variations of result. Thus Zuntz and Hagemann⁶ found in the horse a slight fall of mean pressure, but sometimes a slight rise with moderate work. In the dog, on the other hand, Tangl and Zuntz⁷ always found a rise of from 20 to 30 mm. of mercury with active exercise; but when the dog was made to run very rapidly in the treadmill so that distinctly labored breathing developed, enormously high mean pressures of 275 mm. of mercury were recorded. In the latter case, the relaxation period of the muscle was probably not long enough to permit the blood to flow through in any quantity, so that the great muscular outlet from the

aorta was temporarily blocked off. These direct measurements, however, suffice to show that moderate muscular activity causes only a slight change of mean arterial pressure and that change usually an increase of from 20 to 30 millimeters of mercury; but that certain forms of muscular activity may result in pressures which must be looked upon as distinctly dangerous.

Upon man I would next call attention to Bowen's⁸ very careful measurements of systolic pressure, during work on a stationary bicycle, the work being described as "just vigorous enough to satisfy the needs of a healthy man who is not in training for athletics." He found that the systolic pressure rose from 130 mm. of mercury to a maximum of 180 mm. within the first five or ten minutes; after this there was a fall to a plateau of 165 or 170 mm., or even a continuous but gradual fall throughout the thirty-five minutes of the work. After the cessation of the work there was a sudden fall to or even below the normal, followed by a return to normal within ten minutes. Those interested in the subject will find Bowen's paper very suggestive.

Lastly I should mention McCurdy's⁹ measurements of systolic pressure during the maximal effort of the ordinary gymnasium test of strength of legs. The pressure was first raised in the brachial armlet to 500 mm. of mercury, or thereabouts, and then rapidly lowered during the effort until the radial pulse could be felt. This method would give somewhat low records for systolic brachial pressure, but even then pressures of from 175 to 265 mm. of mercury were recorded. The form of effort reproduced the conditions of

⁶ Zuntz and Hagemann, "Stoffwechsel des Pferdes," 387 foll., Berlin, 1898.

⁷ Tangl and Zuntz, *Pflüger's Archiv*, LXX., 554, 1898.

⁸ Bowen, *American Journal of Physiology*, XI., 59, 1904.

⁹ McCurdy, *American Journal of Physiology*, V., 95, 1901.

forced expiration with closed glottis and it was found that this act alone (without the lifting) caused a similar rise. I can confirm this statement from experiments made in my own laboratory.

These facts are enough to show the extent to which certain forms of muscular activity may raise arterial pressure and we can not but regard this condition, even in the young, as a source of danger. The risk of cardiac dilatation, valvular insufficiency and injury to the arterial wall have been frequently pointed out, and it does not seem that the need for the utmost caution is put aside by the argument that investigation fails to show bad effects on health among those who have engaged in athletic contests in the past. Meylan's* very careful and satisfactory study of the Harvard oarsmen from 1852 to 1892, inclusive, undoubtedly shows marked freedom of these men from cardiac or other vascular troubles in later life, and force the conclusion that this most vigorous of athletic trainings is consistent with the subsequent good health of those who "make the crews." But these are the picked men, physically, of the university and the facts only show that with proper training and under proper medical supervision these picked men may engage in such work without harmful after-effects. But it is one thing to supply adequate medical supervision to a team or crew, and quite a different thing to supply it to a large student body engaging in athletic training; for no medical supervision can be regarded as adequate unless it detects the signs of mischief before it has gone beyond the possibility of repair. In the absence of such supervision it is simply common every-day prudence to keep physical effort well within the bounds of safety.

* Meylan, "Harvard University Oarsmen," *Harvard Graduates' Magazine* and *American Physical Education Review*, March and June, 1904.

The best gymnasium instructors watch carefully for signs of strain, such as skin pallor, labored breathing and the like, during a run and diminish at once the intensity of the work. And in doing so they are only putting into practise the hygienic principle which we have already drawn from the consideration of the probable extent of adaptation of the race as a whole to muscular activity. The average man or woman, the average boy or girl, is not adapted for extreme effort, and it is not proved by experiment or experience that, in such cases, training can supply what heredity has failed to furnish.

Passing to the second condition of strain imposed upon the organism by athletic activities, that of vigorous but not supreme effort continued over longer periods of time, I shall cite only the observations¹ made for three years upon contestants in the Marathon Race held annually under the auspices of the Boston Athletic Association. These show that at the close of the twenty-four mile race (two and one half to three hours) there was always an enlargement of the heart with a systolic murmur (which, however, Larrabee hesitates to attribute to mitral incompetence), that all the signs pointed toward lowered mean blood-pressure; that the blood counts showed "a leucocytosis corresponding in intensity and type with that observed in various inflammatory diseases"; and that the urine invariably contained traces of albumin and more or less blood.

This presents to us the picture of the organism struggling with the conditions of marked general fatigue, especially in the working of the heart and of the vasomotor mechanism. The circulation is being maintained under extremely unfavorable conditions and presents every sign of venous congestion with its resulting inter-

¹ Blake, Larrabee and others, *Boston Medical and Surgical Journal*, CLXVIII., 195, 1903.

ference in the work of the kidneys. It should also be pointed out that even though arterial pressure is subnormal, yet a weakened heart working against comparatively low pressure may be in as great danger as a strong and fresh heart working against high pressure. The conditions may, it is true, be only transitory; they may pass away without lasting ill effects; but they are all distinctly unfavorable conditions in the organism, and we are not justified in looking upon them as other than warnings which must be heeded in formulating proper systems of physical training for the masses.

It is, of course, easy to exaggerate these dangers and it is difficult even to state them clearly and fairly without running the risk of being misunderstood. I should be the last man in the world to advocate the banishment of athletic activities from college life. I would not be understood to discourage new forms of physical exercise merely because they are new and have not formed part of the ancestral activities to which the adaptation of the organism is most perfect. I believe in the active life, in the cultivation of greater physical strength and endurance with all classes and all ages; but let us do this with full understanding of the risks involved, always with due reference to securing in each individual the maximal efficiency in subsequent life, and above all with the determination to provide for the masses the best possible physical training.

UNIVERSITY OF VIRGINIA

CURRENT PROGRESS IN CONSERVATION WORK

THE Proceedings of the Conference of Governors on the conservation of the natural resources of the country, held in the White House, Washington, May 13-15, 1908, have just been issued in a volume of

xxxv + 451 pages. The bulk of the edition is distributed by senators and representatives; the smaller portion designed for distribution by the President among the governors and other conferees is in course of distribution under the direction of ex-President Roosevelt by the Joint Committee on Conservation (Hon. Gifford Pinchot, chairman).

The National Conservation Commission, appointed by the President on June 8 last pursuant to action at the Governors' Conference, held a working session during the first week in December last, at which an inventory of the resources of the country was discussed and a report adopted; during the second week in December the inventory and report were considered at the Joint Conference of State and National commissions and commissions or committees appointed by national organizations. The Joint Conference approved and supplemented the papers, which were duly submitted to the President and were by him in January transmitted to Congress with an approving message. The inventory is the most complete quantitative statement of natural resources ever prepared for any country. After some delay, publication was authorized by Congress, and the matter is now in type and undergoing proof revision. It will form two volumes, aggregating some 1,700 pages. Provision has not yet been made for adequate distribution.

The complete preliminary Report of the Inland Waterways Commission (which body arranged for the Governors' Conference and the subsequent steps in the conservation movement) has been in the hands of the printer for several months, completion being delayed by extensive proof revision, especially of the extended statistical matter prepared in the office of Hon. Herbert Knox Smith, Commissioner of Corporations. The matter is now on

the press, and will be issued within a few days in a volume of vii + 703 pages. The bulk of the edition will be distributed by senators and representatives; a limited number of copies being held for the use of experts.

Pursuant to the Joint Conference in December, President Roosevelt invited Canada and Mexico to join the United States in a joint movement for taking stock of the natural resources of the North American continent. The neighboring nations accepted with alacrity, and each designated three commissioners to meet in Washington with a like number of American commissioners on February 18; and at the instance of the British Ambassador the colony of Newfoundland was also represented. This "North American Conservation Conference" was signally harmonious, and constructive ideas prevailed throughout the deliberations. These continued until February 23, and resulted in the appended *Declaration of Principles*.

A specially noteworthy feature is the unanimous opinion that the time has come for rendering the conservation movement world-wide in scope. When this opinion was submitted to President Roosevelt, he promptly responded by addressing invitations to all civilized nations to join in a conference devoted to consideration of the world's natural resources, to be held at The Hague at such date as may be found generally convenient—if practicable, about September next. Replies (without exception favorable) are arriving in due course; the French government has already taken formal action, and several other nations have announced that action is under way.

During the closing days of the Sixtieth Congress the following amendment was added to the Sundry Civil Bill:

Sec. 9. That hereafter no part of the public moneys, or of any appropriation heretofore or hereafter made by Congress, shall be used for the

payment of compensation or expenses of any commission, council, board, or other similar body, or any members thereof, or for expenses in connection with any work or the results of any work or action of any commission, council, board, or other similar body, unless the creation of the same shall be or shall have been authorized by law; nor shall there be employed by detail, hereafter or heretofore made, or otherwise personal services from any executive department or other government establishment in connection with any such commission, council, board or other similar body.

When the bill was enacted and submitted to the President for signature, he disapproved this item in a memorandum attached to and forming a part of the Act (and which has received wide attention through the press), as follows:

I have hesitated long before affixing my signature to this bill, and if it were earlier in the session, or if the bill contained a less number of important propositions of benefit to the country, I should certainly not sign it. Moreover, if section 9 of the bill, to which I subsequently refer, were operative according to its evident intent, I should be forced to veto the bill anyhow. But I have concluded that this section is not operative to the extent that its framers evidently hoped, and that the mischief it will cause, though appreciable, can be sufficiently remedied by the action of the Executive to warrant my permitting the bill to become a law, in view of all the considerations surrounding the case.

Section 9 of the act contains a provision far more damaging to the interests of the public. This attempts to prohibit the use of any government funds or the detail of any government clerks to help the work of any commission, council or board, unless the same is specifically authorized by previous congressional action. This could certainly only result in hampering efficient government work. But as the purpose of the attempt in its entirety is clearly an invasion of executive prerogative, and unconstitutional and void, it is only very partially successful. The provision is obviously aimed at such commissions or boards as, for instance, the Conservation Commission, the Country Life Commission, the Council of Fine Arts, the General Board of the Navy and the Joint Board of the Army and Navy, not to speak of such boards as the National Advisory Board on Structural Material, the board of reference in

connection with the pure food law and scores of others, none of which were first authorized by Congress, but all of which were called together by the Executive for the purpose of public service; for the purpose of rendering to our people sorely needed service which could not and would not otherwise have been rendered. So far as the various army and navy boards are concerned, the attempt is fortunately futile, and represents merely failure in an effort to subordinate purely military and national considerations to small personal or political considerations. The President has under the Constitution the sole power to direct the use of the officers of the army and navy, always provided he acts within the limits set by the Constitution. The Congress can no more forbid the President to use the services of officers or employees when they act in concert as a board or council than it can forbid him to use their services when they act as individuals.

The chief object of this provision, however, is to prevent the Executive repeating what it has done within the last year in connection with the Conservation Commission and the Country Life Commission. It is for the people of this country to decide whether or not they believe in the work done by the Conservation Commission and by the Country Life Commission. If the people of this country do not believe in the conservation of our natural resources; if they do not believe in developing our waterways and protecting our forests; if they do not believe in the betterment of life on the farm, and in upholding the interests of the farmers; if they are willing to go on in the old course of squandering the effects of our children's children; then they will uphold the action of those in Congress who are responsible for this provision. If they believe in improving our waterways, in preventing the waste of soil, in preserving the forests, in thrifty use of the mineral resources of the country for the nation as a whole rather than merely for private monopolies, in working for the betterment of the condition of the men and women who live on the farms, then they will unstintedly condemn the action of every man who is in any way responsible for inserting this provision, and will support those members of the legislative branch who opposed its adoption. I would not sign the bill at all if I thought the provision entirely effective. But the Congress can not prevent the President from seeking advice. Any future President can do as I have done, and ask disinterested men who desire to serve the people to give this service free to the people through

these commissions. This action taken by the Congress hampers and renders more difficult the work of such commissions, and entails a greater sacrifice in time and money upon the public-spirited men who disinterestedly and without any recompense have served or may serve on these commissions. But the Congress can only hamper and render more difficult, it can not stop this work. The Executive can continue to appoint these commissions and can make exactly the use of them that I have made in the past, although, owing to the Congress, a greater burden will be put upon them.

The republican platform last year said: "We endorse the movement inaugurated by the administration for the conservation of natural resources. . . . No obligation of the future is more insistent and none will result in greater blessings to posterity." The democratic platform said: "We repeat the demand for internal development and for the conservation of our natural resources, the enforcement of which Mr. Roosevelt has . . . sought."

My successor, the President-elect, in a letter to the Senate Committee on Appropriations, asked for the continuance and support of the Conservation Commission. The Conservation Commission was appointed at the request of the governors of over forty states, and almost all of these states have since appointed commissions to cooperate with the national commission. Nearly all the great national organizations concerned with natural resources have been heartily cooperating with the commission.

With all these facts before it, the Congress has refused to pass a law to continue and provide for the commission; and it now passes a law with the purpose of preventing the Executive from continuing the commission at all. The Executive, therefore, must now either abandon the work and reject the cooperation of the states, or else must continue the work personally and through executive officers whom he may select for that purpose.

When I speak of the Congress I, of course, mean those members of the Congress who are responsible for this provision of the bill, and I emphatically do not mean those public-spirited members who have striven to prevent the incorporation in the bill of this provision. To the Congressmen who in this and similar matters have stood by the interests of the public, the interests of those whom Abraham Lincoln called "the plain people," the heartiest support is owing. But I call the atten-

tion of those who are responsible for putting in this provision to a fundamental fact which is often ignored in discussing and comparing the action of the executive and the action of the legislative branches of the government. Neither one is responsible to the other. Each must act as its wisdom dictates. But each is responsible to the people as a whole. It is for the people to decide whether they are represented aright by any given servant; and one element in enabling them to reach a decision must be that public servant's record in such a case as this.

At the Joint Conference on Conservation, in December, a resolution was offered providing for a joint committee of nine to prepare a plan of cooperation among conservation commissions, six members to be appointed from state commissions and three from the National Commission; in the course of discussion, provision was made for including also the chairman and secretary of the latter body (Hon. Gifford Pinchot and Mr. Thomas R. Shipp) and in this form the resolution was adopted. The first formal meeting of this joint committee was set for March 5; and on that and the ensuing day the committee met and framed a plan for joint work which will be circulated during the present month. On March 6 several members of the committee, headed by ex-Governor Pardee, of California, and accompanied by Governors Deneen, of Illinois, Willson, of Kentucky, and Quinby, of New Hampshire, submitted the general plan for continuing the conservation work to President Taft, who reiterated his frequently expressed intention of continuing the task begun by his predecessor, and using every effort to secure legislative action. In the course of the meeting of the Joint Committee on Conservation, it was found that thirty-seven states have appointed state conservation commissions, and that some thirty organizations of national character have appointed committees of like character and purpose. Definite arrangements were made for coordi-

nating the work of these organizations in such manner as to yield increasingly accurate inventories of the natural sources of national prosperity and perpetuity. Messrs. Pinchot and Shipp, respectively, were made chairman and secretary of the committee, and headquarters were established in the Wyatt building, Washington, D. C.

W J MCGEE

NORTH AMERICAN CONSERVATION CONFERENCE DECLARATION OF PRINCIPLES

We recognize the mutual interests of the nations which occupy the continent of North America and the dependence of the welfare of each upon its natural resources. We agree that the conservation of these resources is indispensable for the continued prosperity of each nation.

We recognize that the protection of mutual interests related to natural resources by concerted action, without in any way interfering with the authority of each nation within its own sphere, will result in mutual benefits, and tend to draw still closer the bonds of existing good will, confidence and respect. Natural resources are not confined by the boundary lines that separate nations. We agree that no nation acting alone can adequately conserve them, and we recommend the adoption of concurrent measures for conserving the material foundations of the welfare of all the nations concerned, and for ascertaining their location and extent.

We recognize as natural resources all materials available for the use of man as means of life and welfare, including those on the surface of the earth, like the soil and the waters; those below the surface, like the minerals; and those above the surface, like the forests. We agree that these resources should be developed, used and conserved for the future, in the interests of mankind, whose rights and duties to guard and control the natural sources of life and welfare are inherent, perpetual and inalienable. We agree that those resources which are necessities of life should be regarded as public utilities, that their ownership entails specific duties to the public, and that as far as possible effective measures should be adopted to guard against monopoly.

Public Health.—Believing that the conservation movement tends strongly to develop national efficiency in the highest possible degree in our respective countries, we recognize that to accom-

plish such an object with success, the maintenance and improvement of public health is a first essential.

In all steps for the utilization of natural resources considerations of public health should always be kept in view.

Facts which can not be questioned demonstrate that immediate action is necessary to prevent further pollution, mainly by sewage, of the lakes, rivers and streams throughout North America. Such pollution, aside from the enormous loss in fertilizing elements entailed thereby, is an immediate and continuous danger to public health, to the health of animals, and, when caused by certain chemical agents, to agriculture. Therefore we recommend that preventive legislation be enacted.

Forests.—We recognize the forests as indispensable to civilization and public welfare. They furnish material for construction and manufacture, and promote the habitability of the earth. We regard the wise use, effective protection, especially from fire, and prompt renewal of the forests on land best adapted to such use, as a public necessity and hence a public duty devolving upon all forest owners alike, whether public, corporate or individual.

We consider the creation of many and large forest reservations and their permanent maintenance under government control absolutely essential to the public welfare.

We favor the early completion of inventories of forest resources, in order to ascertain the available supply and the rate of consumption and reproduction.

We recommend the extension of technical education and practical field instruction in forest conservation, afforestation and reforestation, so as to provide efficient forest officers whose knowledge will be available for necessary public information on these subjects.

Believing that excessive taxation on standing timber privately owned is a potent cause of forest destruction by increasing the cost of maintaining growing forests, we agree in the wisdom and justice of separating the taxation of timber land from the taxation of the timber growing upon it, and adjusting both in such a manner as to encourage forest conservation and forest growing.

We agree that the ownership of forest lands, either at the headwaters of streams or upon areas better suited for forest growth than for other purposes, entails duties to the public, and that such lands should be protected with equal effect-

iveness, whether under public or private ownership.

Forests are necessary to protect the sources of streams, moderate floods and equalize the flow of waters, temper the climate and protect the soil; and we agree that all forests necessary for these purposes should be amply safeguarded. We affirm the absolute need of holding for forests, or reforesting, all lands supplying the headwaters of streams, and we therefore favor the control or acquisition of such lands for the public.

The private owners of lands unsuited to agriculture, once forested and now impoverished or denuded, should be encouraged by practical instruction, adjustment of taxation, and in other proper ways, to undertake the reforesting thereof.

Notwithstanding an increasing public interest in forestry, the calamitous and far-reaching destruction of forests by fire still continues and demands immediate and decisive action. We believe that systems of fire guardianship and patrol afford the best means of dealing adequately with fires which occur, whether from natural causes, such as lightning, or in other ways; but we affirm that in addition thereto effective laws are urgently needed to reduce the vast damage from preventable causes.

Apart from fire, the principal cause of forest destruction is unwise and improvident cutting, which, in many cases, has resulted in widespread injury to the climate and the streams. It is therefore of the first importance that all lumbering operations should be carried on under a system of rigid regulation.

Waters.—We recognize the waters as a primary resource, and we regard their use for domestic and municipal supply, irrigation, navigation and power as interrelated public uses and properly subject to public control. We therefore favor the complete and concurrent development of the streams and their sources for every useful purpose to which they may be put.

The highest and most necessary use of water is for domestic and municipal purposes. We therefore favor the recognition of this principle in legislation and, where necessary, the subordination of other uses of water thereto.

The superior economy of water transportation over land transportation, as well as its advantages in limiting the consumption of the non-renewable resources, coal and iron, and its effectiveness in the promotion of commerce, are generally acknowledged. We therefore favor the development of inland navigation under general plans adapted

to secure the uniform progress of the work and the fullest use of the streams for all purposes. We further express our belief that all waterways so developed should be retained under exclusive public ownership and control.

We regard the monopoly of waters, and especially the monopoly of water power, as peculiarly threatening. No rights to the use of water powers in streams should hereafter be granted in perpetuity. Each grant should be conditioned upon prompt development, continued beneficial use, and the payment of proper compensation to the public for the rights enjoyed; and should be for a definite period only. Such period should be no longer than is required for reasonable safety of investment. The public authority should retain the right to readjust at stated periods the compensation to the public and to regulate the rates charged, to the end that undue profit or extortion may be prevented.

Where the construction of works to utilize water has been authorized by public authority and such utilization is necessary for the public welfare, provision should be made for the expropriation of any privately owned land and water rights required for such construction.

The interest of the public in the increase of the productiveness of arid lands by irrigation and of wet lands by drainage is manifest. We therefore favor the participation of the public to secure the complete and economical development and use of all water available for irrigation and of all lands susceptible of profitable drainage, in order to ensure the widest possible benefit. Special projects should be considered and developed in connection with a general plan for the same watershed. In the matter of irrigation, public authority should control the headwaters and provide for the construction of storage reservoirs and for the equitable distribution and use of the stored water.

Lands.—We recognize land as a fundamental resource, yielding the materials needed for sustaining population, and forming the basis of social organization. Increase in the productivity of the soil is a growing need, and the possession of the land by the men who live upon it not only promotes such productivity, but is also the best guarantee of good citizenship. In the interest of the homemaker, we favor regulation of grazing on public land, the disposal of public lands to actual settlers in areas each sufficient to support a family, and the subdivision of excessive holdings of agricultural or grazing land, thereby preventing monopoly.

The preservation of the productivity of the soil is dependent upon rotation of crops, fertilization by natural or artificial means and improved methods in farm management. The quantity and quality of crops are also dependent upon the careful selection of seed. We therefore favor the distribution by government bureaus of scientific and practical information on these points, and we urge upon all farmers careful attention thereto.

The national importance for grazing of non-irrigable public lands too dry for cultivation and the public loss occasioned by overgrazing are generally acknowledged. We therefore favor government control of such lands in order to restore their value; promote settlement and increase the public resources.

The first requisite for forest or other covering which will conserve the rainfall and promote regularity of water flow is the retention of the soil upon watersheds. We therefore favor the construction of such artificial works as may effect this purpose and the encouragement thereof by remission of taxes, government cooperation, or other suitable means.

Minerals.—We recognize the mineral resources as forming the chief basis of industrial progress, and regard their use and conservation as essential to the public welfare. The mineral fuels play an indispensable part in our modern civilization. We favor action on the part of each government looking towards reduction of the enormous waste in the exploitation of such fuels, and we direct attention to the necessity for an inventory thereof. Such fuels should hereafter be disposed of by lease under such restrictions or regulations as will prevent waste and monopolistic or speculative holding, and supply the public at reasonable prices.

We believe that the surface rights and underground mineral rights in lands should be separately dealt with so as to permit the surface of the land to be utilized to the fullest extent, while preserving government control over the minerals.

Regulations should be adopted looking to the most economical production of coal and other mineral fuels and the prolongation of the supply to the utmost. We favor also the substitution of water power for steam or other power produced by the consumption of fuel.

Great economy in the use of fuel has resulted in the past from the application of scientific inventions and the use of improvements in machinery, and further progress can be made in the same direction. We therefore recommend that all possible encouragement and assistance be given in

the development and perfecting of means whereby waste in the consumption of fuel can be reduced.

The loss of human life through preventable mining accidents in North America is excessive. Much needless suffering and bereavement results therefrom. Accompanying this loss there is great destruction of valuable mineral property and enhancement of the cost of production. The best method of eliminating these known and admitted evils lies in the enactment and strict enforcement of regulations which will provide the greatest possible security for mine workers and mines. We therefore favor the scientific investigation of the whole subject of mine accidents by the governments participating in this conference, the interchange of information and experience and the enactment and enforcement of the best regulations that can be devised.

Mineral fertilizers should not be monopolized by private interests, but should be so controlled by public authority as to prevent waste and to promote their production in such quantity and at such price as to make them readily available for use.

Protection of Game.—We recognize that game preservation and the protection of bird life are intimately associated with the conservation of natural resources. We therefore favor game protection under regulation, the creation of extensive game preserves and special protection for such birds as are useful to agriculture.

Conservation Commissions.—The action of the President of the United States in calling this first conference to consider the conservation of the natural resources of North America was in the highest degree opportune, and the proceedings which have followed, and the information mutually communicated by the representatives assembled, have, we believe, been conducive to the best interests of the countries participating. To derive the greatest possible benefit from the work which has already been done, and to provide proper and effective machinery for future work, there should be established in each country a permanent conservation commission.

When such conservation commissions have been established, a system of intercommunication should be inaugurated, whereby, at stated intervals, all discoveries, inventions, processes, inventories of natural resources, information of a new and specially important character, and seeds, seedlings, new or improved varieties, and other productions which are of value in conserving or improving any natural resource shall be trans-

mitted by each commission to all of the others, to the end that they may be adopted and utilized as widely as possible.

World Conservation Conference.—The conference of delegates, representatives of the United States, Mexico, Canada and Newfoundland, having exchanged views and considered the information supplied from the respective countries, is convinced of the importance of the movement for the conservation of natural resources on the continent of North America, and believes that it is of such a nature and of such general importance that it should become worldwide in its scope, and therefore suggests to the President of the United States of America that all nations should be invited to join together in conference on the subject of world resources and their inventory, conservation and wise utilization.

GIFFORD PINCHOT,
ROBERT BACON,
JAMES R. GARFIELD,

Commissioners Representing the United States.

RÓMULO ESCOBAR,
MIGUEL A. DE QUEVEDO,
CARLOS SELLERIER,

Commissioners Representing the Republic of Mexico.

SYDNEY FISHER,
CLIFFORD SIFTON,
HENRI S. BÉLAND,

Commissioners Representing the Dominion of Canada.

E. H. OUTERBRIDGE,
Commissioner Representing the Colony of Newfoundland.

Attest:

ROBERT E. YOUNG,
THOMAS R. SHIFF,

Secretaries of the Conference.

WASHINGTON, D. C., February 23, 1909

SCIENTIFIC NOTES AND NEWS

THE centenary of the birth of Darwin was commemorated at Syracuse University on March 19, by a meeting held under the auspices of the Syracuse Chapter of Sigma Xi, the Onondaga Academy of Science, the Syracuse Academy of Medicine, the Syracuse Botanical Club, the University Biological Association and the University Geological Club. Addresses were made as follows: "Darwin and Zoology," by Professor Charles W. Hargitt; "Darwin and Botany," by Professor William L. Bray; "Darwin and Geology," by Dr. John M. Clarke, state geologist, Albany.

WASHBURN COLLEGE and the Kansas Academy of Science celebrated the centenary of

Darwin's birth on March 26, the program being: "Darwinism and Experimentation," Dr. D. T. MacDougal, director, department botanical research, Carnegie Institution of Washington; "Evolution of Organisms in Relation to Environment," Professor W. L. Tower, department of zoology, University of Chicago.

THE Wellesley College Science Club held its one hundredth meeting on March 9 in the Whittin Observatory, when the program was devoted to Charles Darwin. Dr. Robertson gave an account of the status of biology before Darwin's time and the changes wrought by him. Dr. Ferguson followed, giving an account of the influence of Darwin's work on botanical science. Dr. Wiegand then gave a paper on "Modern Theories of the Origin of Species and their Relation to Natural Selection." Professor Hayes was the last speaker.

DARWIN memorial exercises were held at the Michigan Agricultural College on March 4, with the following program: "Early Impressions of Darwinism," Dr. W. J. Beal; "Darwin, the Worker," Professor W. B. Barrows; "Darwin's Influence on Thought," Dr. R. M. Wenley.

THE daily papers state that it is proposed to offer the ambassadorship to Great Britain to President Eliot after his retirement from the presidency of Harvard University. Mr. Eliot, who is at present making addresses in the south, reached his seventy-fifth birthday on March 20.

A BANQUET in honor of President Angell was given in New York City on March 19 by alumni of the University of Michigan.

THE seventh annual meeting of the South African Association for the Advancement of Science will be held at Bloemfontein at the end of September under the presidency of Sir Hamilton J. Goold-Adams.

DR. SVEN HEDIN has lectured in the presence of Emperor William before the Berlin Geographical Society, which awarded to him its Humboldt medal. He has also lectured at the Sorbonne, Paris.

PROFESSOR W. M. DAVIS, of Harvard University, has finished his courses at Berlin and

has gone to Scotland to deliver a series of lectures on geology before Edinburgh University.

SIR F. RAY LANKESTER will deliver the Huxley lecture for the present session at Birmingham University.

PROFESSOR WM. T. SEDGWICK, of the Massachusetts Institute of Technology, expects to leave Boston in the middle of April to make a number of addresses in the middle west.

At the meeting of the Society of Arts of the Massachusetts Institute of Technology on March 25, President R. S. Woodward, of the Carnegie Institution, was expected to lecture on the work of the institution. On April 5 Professor George E. Hale, director of the Solar Observatory of the Carnegie Institution, is announced to lecture on "Solar Cyclones and Magnetic Fields."

DR. A. M. STEIN will give a lecture under the auspices of the Royal Asiatic Society on Tuesday, March 30, on his recent explorations in eastern Turkestan.

MR. D. CARRUTHERS, who took part in the British Museum expedition to Ruwenzori as a zoological collector under Mr. R. B. Woosnam in 1906, is at present exploring central Arabia.

DR. CHEVALIER, who since the conclusion of his expedition to the upper Shari basin, has been on the Guinea coast, has started on a new expedition to west Africa.

THE National Society of Acclimatization of France has conferred on Mr. W. Percival Westell its bronze medal in recognition of his natural history writings.

WILLIAM STUART, for the past ten years professor of horticulture in the Agricultural Department of the University of Vermont, has received an appointment in the plant bureau of the Department of Agriculture, Washington, and will enter upon his new duties at the close of the college year.

MRS. TYNDALL, in pursuance of the wishes of the late Professor Tyndall, who was a member of the Royal Commission appointed in 1879 to inquire into the causes of explosions in coal mines and who took a deep interest in problems concerning the safety of miners, proposes to found a gold medal to be awarded

annually for inventions tending to diminish danger and preserve life among those engaged in mining operations. The adjudication of this "Tyndall Medal" is to be placed in the hands of the managers of the Royal Institution, where Professor Tyndall occupied the chair of Natural Philosophy from 1853 to 1887.

It is proposed to endow as a memorial to the late Dr. William T. Bull an institution for surgical research to be connected with the College of Physicians and Surgeons, Columbia University, from which Dr. Bull was graduated in 1872, and where he served for many years as professor of surgery. It is further stated that Mrs. Bull proposes to erect a memorial hospital for the treatment of tuberculosis.

PROFESSOR MARK VERNON SLINGERLAND, who held the chair of economic entomology at Cornell University, and was an authority on the injurious insects of the United States, died at Ithaca on March 10, at the age of forty-four years.

MAJOR EDMUND LEWIS ZALINSKI, U.S.N., retired, at one time professor of military science in the Massachusetts Institute of Technology, known for experimental work on high explosives, died in New York City on March 10, at the age of fifty-nine years.

DR. S. H. LAURIE, emeritus professor of education in the University of Edinburgh, died in Edinburgh on March 2 at the age of seventy-nine years.

DR. EMIL ERLENMEYER, formerly professor of chemistry in the Munich Technical Institute, has died at the age of eighty-three years.

THE deaths are also announced of M. Frédéric Rauh, professor of philosophy at Sorbonne, and Senhor Barbosa Rodrigues, author of several works on the Brazilian flora.

A RECENT list of the publications of the United States Geological Survey gives the titles of 977 volumes. This list does not include the separate chapters from the annual volume on mineral resources, which make up several hundred pamphlets.

It is now finally settled that the Forest Service Experimental Laboratory will be situ-

ated at the University of Wisconsin. Opportunity was given to Michigan and Minnesota to present the advantages of those institutions, but the original plan will be carried out. Work on the new laboratory, which is to be located on Camp Randall near the agricultural buildings and the new site of the engineering group, will be begun at an early date. The university provides the site and a \$30,000 building, while the forest service is to equip the laboratory at a cost of \$14,000 and to provide the entire staff of investigators, whose salaries will aggregate \$28,000 a year. The laboratory is to be available for students and faculty of the university for research work, and the members of the staff are to deliver lectures on forestry and allied subjects to students of the university. A course for forest rangers is to be provided by the university in connection with the experiment station as soon as it is completed. The work of the laboratory is to include tests of various kinds of wood for paper pulp, for building material, for the distillation of turpentine, alcohol and resin from wood waste.

APPROPRIATIONS FOR THE UNITED STATES BUREAU OF EDUCATION

THE estimates of appropriations for the United States Bureau of Education for the fiscal year ending June 30, 1910, as transmitted to Congress, included under the general head of salaries estimates for additional employees as follows: Expert in higher education, \$4,000; expert in industrial education, \$3,000; expert in the welfare of children, \$3,000; editor, \$2,000; additional clerks, \$12,100. Of the new employees requested, Congress made provision for an editor at \$2,000; one clerk at \$1,200; and one clerk at \$1,000. The salary of the Commissioner of Education was increased from \$4,500 to \$5,000, making a total increase in the appropriations for the general work of the Bureau of \$4,700 over the appropriations for the current fiscal year. The requests for a lump sum appropriation of \$40,000 for educational investigations; for an increase of \$1,500 in the appropriation for the library; for an increase of \$3,000 in the fund for collecting statistics; and of an ap-

appropriation of \$39,000 for rent, metal shelving, additional furniture, and removal of the Bureau to new quarters, did not receive the favorable consideration of Congress.

The appropriation for the education of the natives of Alaska remains the same as for the present year, \$200,000. The appropriation for reindeer in Alaska was reduced, on the recommendation of the Commissioner of Education, from \$15,000 to \$12,000. Provision was made by Congress for the designation of employees of the Alaska School service as special peace officers to assist in the enforcement of law in Alaska.

UNIVERSITY AND EDUCATIONAL NEWS

GIFTS amounting to \$176,960 from Mr. John D. Rockefeller to the University of Chicago were announced on March 16 by President Judson at the recent convocation. The larger part is for the College of Education.

THE *New York Evening Post* states that the University of Missouri will receive \$500,000, for the assistance of needy students, by the will of Charles R. Gregory, of St. Louis, who recently died in Paris.

THE Weyerhaeuser interests of St. Paul have given to the University of Minnesota 2,200 acres of land in Carlton County for the use of experiments by the forestry department.

IN accordance with the terms of the will of the late Dr. Julian Hunter that the name of his father—Joseph Hunter—should be perpetuated in connection with his bequest to Sheffield University, the council has resolved to call the chair of pathology in the university the "Joseph Hunter Chair of Pathology." It is proposed with the Hunter bequest (amounting to £15,000) to establish a chair of economics and to carry on the department of philosophy and logic under a lecturer.

THE Goldsmiths' Company will renew for a further period of three years their annual grant of £5,000 towards the maintenance of Goldsmiths' College, New-cross.

MR. R. O. KING, a former graduate of the faculty of applied science and a demonstrator in physics at McGill University, has estab-

lished a fellowship in physics of the value of \$600.

EFFORTS are being made to collect \$500,000 to establish a medical school at Pekin.

It is reported in the daily papers that thirteen college presidents, whose institutions are among those classed as denominational, have presented a memorial to Dr. Henry S. Pritchett, president of the Carnegie Foundation. The memorial urges that many colleges which were founded by religious bodies are to-day free to men of all creeds and do not teach particular dogmas or require any particular beliefs by students or professors. They are, therefore, it is declared, practically non-sectarian.

MR. GEORGE R. PARKIN has sent a letter to members of the American Committees of selection for the Rhodes Scholarships at Oxford, stating that the trustees of the trust have decided that any candidate from the United States who has passed the qualifying examination in Latin and mathematics shall be eligible, even though he may not have passed in Greek. He will, however, be required to pass the examination in Greek before going into residence or at all events before receiving a degree.

THE American Ethical Union will hold its summer school at the University of Wisconsin from June 28 to July 24, under the direction of Dr. Felix Adler, of Columbia University.

THE inauguration of Professor A. Lawrence Lowell as president of Harvard University, will occur some time in October; the exact date has not been set.

THE president's European fellowship of Bryn Mawr College has been awarded to Miss Grace Potter Reynolds, B.A. (Smith), M.A. (Columbia) and formerly assistant in chemistry at Barnard College, Columbia University.

At the School of Pharmacy of Western Reserve University, Professor W. H. Haake has resigned as professor of materia medica and is succeeded by Dr. Torald Sollmann.

DR. DAVID FRASER HARRIS has been appointed lecturer in physiology at Birmingham University to succeed Dr. Rhodes.

DISCUSSION AND CORRESPONDENCE

NOTE ON THE SPECTRUM OF MARS

I THINK that Professor Very's article on "The Presence of Water Vapor in the Atmosphere of Mars," though written with the kindest feelings for all concerned, is certain to convey a wrong impression as to the observations made by Huggins, Vogel and others in the sixties and seventies and by myself in 1894-5. The pioneer observers believed they saw in the spectrum of Mars the modifying influences of oxygen and water vapor in its atmosphere. I held, and published, the opinion that "the polar caps on Mars are conclusive evidence of an atmosphere and aqueous vapor" on that planet;¹ but my spectroscopic observations, made under vastly improved conditions, convinced me that oxygen and water vapor did not exist in sufficient quantities to be detected by the spectroscopic method as then available, for this method is a very insensitive one. The observations by the earlier observers, and by myself, were confined to the spectral region $\lambda 5400$ to $\lambda 6900$. The region of wave-lengths larger than $\lambda 6900$ was entirely too faint for visual study, and in those days we had not the means of photographing it. About two years ago it was discovered that the application of certain chemicals to an ordinary dry-plate would make it quite sensitive to radiations of greater wave-lengths than $\lambda 6900$. In the region thus rendered available, at $\lambda 7175$, is the so-called little "a" band, due to water vapor. It is this band, in a region previously unobserved and unobservable in Mars' spectrum, upon which Professor Very's work is based exclusively. His investigations, therefore, afford no evidence as to the correctness of the early observations.

Now comes the point, omitted by Professor Very, which does bear upon the early observations. The spectrum photographs used by Very (made by Mr. Slipper at Flagstaff) recorded not only the new region containing the band "a," but also the old region $\lambda 5400$ to $\lambda 6900$. Mr. Slipper's published conclusion,

as based on his series of seven spectrum photographs, is that "Aside from reinforcement of the 'a' band (at $\lambda 7175$), the spectrum of Mars shows no selective absorption not found in that of the moon photographed under the same conditions";² that is, the effects of oxygen and water vapor on Mars were no more visible in the region $\lambda 5400$ - $\lambda 6900$ of the spectrum than were the effects of oxygen and water vapor existing on the moon!

Only those who have seen Mr. Slipper's original negatives can judge of their value; but whatever their value, they are absolutely confirmatory of my visual observations of 1894, of my photographic observations of 1895, of Professor Keeler's photographic observations of 1897; and as absolutely opposed to the observations of Huggins, Vogel, Maun-der and others as my own observations were. Readers of Very's article would get exactly the opposite view.

If Mr. Slipper, observing from a high altitude and with little water vapor in our atmosphere to embarrass him, could see no difference between the spectra of Mars and the moon in the region $\lambda 5400$ - $\lambda 6900$, how impotent were the effects of the pioneer observers at sea-level, with small telescopes, looking through ten times as much water vapor as Mr. Slipper and I did; yet, all hail, and nearly all the credit to the pioneers! Their work, though unsuccessful, makes progress possible by succeeding generations of investigators.

W. W. CAMPBELL

MR. HAMILTON,
February 6, 1909

A NEW KIND OF PTARMIGAN

TO THE EDITOR OF SCIENCE: The current *McClure's Magazine* (March, 1909) contains a sonnet which I am sure will entertain the readers of SCIENCE, even though it bears the gruesome title "The Shipwrecked Sailor." It contains this striking (in more senses than one) bit of ornithological news:

Yet he smiled,

Abandoning hope and drowning unaware,

² *Astrophysical Journal*, 28, p. 403, 1908.

¹ SCIENCE, January 29, 1909, p. 191.

² *Astronomy and Astrophysics*, 1894, p. 760.

Till a great sea-bird, tern or ptarmigan,
Caught by the whiteness of his lonely face,
Swooped low exultantly; huge swish of wings
Measuring his body, as he struck him once.
Thud of the ribbed beak, like a call to arms
Stirring the wounded soldier, etc."

What would not Mr. Chapman give for a moving picture of the author's mental image of a ptarmigan? Would it be in order, since Miss Florence Wilkinson is the writer to whom we are indebted for a description of this new species, to call the Ribbed-beaked Ptarmigan, *Lagopus wilkinsoni*?

HUBERT LYMAN CLARK

SCIENCE AND POLITICS IN CUBA

TO THE EDITOR OF SCIENCE: I have just learned that the new Cuban administration has asked for the resignation of all the Americans on the staff of the Cuban Agricultural Experiment Station. This is purely a political move made to supply more places for the horde of hungry office seekers. No comment is needed when a government is willing to make a political football of its only efficient scientific institution. The following is a list of those who have been so suddenly and unjustly deprived of their positions. I know all of these gentlemen personally and am familiar with their work. Many of them are former colleagues. I take a great pleasure in heartily recommending them to any institutions who may have vacancies in these respective lines.

Dr. N. S. Mayo, Chief, Department of Animal Industry.

Mr. J. S. Montgomery, Assistant, Department of Animal Industry.

Professor Wm. T. Horne, Chief, Department of Vegetable Pathology and Entomology.

Mr. J. S. Houser, Assistant, Department of Vegetable Pathology and Entomology.

Professor R. S. Stark, Chief, Department of Chemistry.

Dr. H. Hasselbring, Chief, Department of Botany.

Professor C. F. Austin, Chief, Department of Horticulture.

Mr. C. F. Kinman, Assistant, Department of Horticulture.

F. S. EARLE

SCIENTIFIC BOOKS

Laboratory Notes on Industrial Water Analysis. A Survey Course for Engineers. By ELLEN H. RICHARDS, Instructor in Sanitary Chemistry, Massachusetts Institute of Technology. 8vo, pp. iii + 49. Cloth, 50 cents net (2s. net). New York, John Wiley & Sons; London, Chapman & Hall, Limited. 1908.

The book is written for the use of students of engineering and deals with "boiler waters" principally.

Part I. is divided into five laboratory exercises: First, Classification of a Water as "Scale-forming," "Moderately Scale-forming," or "Corrosive"; second, Determination of "Total Solids," "Incrustants," "Iron" and "Sulphates"; third, "Alkalinity," "Magnesium as Hydrate" and "Permanent Hardness"; fourth, "Action Upon Metals," "Oxygen Consumed" and "Dissolved Oxygen"; fifth, "Remedies for Defects Found in Waters." "Only special methods are considered, leaving out the ordinary analytical processes to be found in text-books."

Part II. is devoted to the preparation of "standard solutions" and to sundry tables useful in water analysis.

The following sentence is well worthy of attention, as it points to a fact often lost sight of: "Water unsatisfactory for one purpose may be, or may be made, quite satisfactory for another."

Mrs. Richards has had such extended experience in matters dealing with water examination that anything from her pen is always of value.

W. P. MASON

A Laboratory Guide for Histology. By IRVING HARDESTY, A.B., Ph.D., with a chapter on Laboratory Drawing, by ADELBERT WATTS LEE, M.D. With 80 illustrations, 2 of which are in colors. Pp. 193. Philadelphia, P. Blakiston's Son & Co. 1908.

That there is a place for such a well-planned, practical series of laboratory outlines for the study of histology and microscopic anatomy as are found in this guide the reviewer has no

doubt. The volume is a timely contribution and is characterized by all the excellencies which one is led to expect from a knowledge of the other publications of this careful and experienced teacher. Pedagogically considered, aside from its lopping off of superfluities, its greatest virtue lies in the manner in which the student is impelled to get at the subject interpretatively instead of blindly following descriptions. The method is not wholly inductive, however, since the student is expected to know what is said in his text-book or lectures on a given subject; nevertheless, through a judicious use of questions he is forced to think for himself and not simply to verify statements.

One great aim of the author has been to do away with the numerous irrelevant procedures at which the student is likely to fritter away his time and to lead him at once to see and to accomplish the real work that is to be done. The main idea has been to have him so utilize his time as to cover thoroughly the greatest possible amount of ground in the time allotted to the course. The outlines are the outgrowth of the author's own experience as a teacher and having been revised and corrected year after year, in their final form they represent, therefore, just what in his experience may most advantageously be undertaken by the average class in histology working three three-hour periods per week throughout one school year.

In case a school can not give three afternoons a week to the course, however, the work is so arranged that it can be given conveniently in two separate years. The reviewer is of the opinion, indeed, that the third section might well be reserved for the second year as it in itself constitutes a complete course in the gross and microscopic anatomy of the central nervous system and the organs of special sense, and includes work of considerably greater difficulty than that of the other two sections.

The author rightfully insists throughout the work upon the importance of having the transition from the macroscopic to the microscopic detail made with sufficient fulness for the student to get a complete mental picture

of the structure as a whole instead of the mere fragments he too often gets when stained and sectioned material chiefly is used.

The arrangement of topics and the classification of structures is made mainly upon an anatomical and functional rather than an embryological basis. The practical utility of such an arrangement would seem sufficient to justify it even though an embryological arrangement would leave the student with a clearer morphological perspective of the general field. For the medical student, at least, the imperative demand is for the functional rather than the morphological conception. The embryological side, however, has not been slighted, for the principles and processes of development are kept well in the foreground and there are frequent demands for the study of sections of embryos and preparations of developing tissues and organs.

A valuable chapter is that by Dr. A. W. Lee on Laboratory Drawing in which a very enlightening discussion of drawing materials and methods is given. As Dr. Lee himself expresses it, "The individual who 'can't draw' has constantly been kept in mind; in fact, this chapter was undertaken solely for his benefit." Such a clear and non-technical discussion of laboratory drawing has long been a desideratum and it should not be reserved for those who study histology merely but should be brought to the attention of all biological students. Original drawings in varying stages of completion are employed as an aid in illustrating more graphically the principles involved. Unfortunately, by what is clearly a typographer's error, the block for figure 13 has been rotated ninety degrees with the result that the parallel which the author intended to show between this and the preceding figure is somewhat obscured.

A few of the seemingly inevitable typographical errors have crept into the volume here and there, but none is of great magnitude. Some of the most noticeable are as follows: page 40, formation for information; page 45, aquamous for squamous; page 54, glyerin for glycerin; page 72, cosmic for osmic, and the same on page 73; page 73, non-modullated for non-medullated; page 139,

Ralando for Rolando, and page 180 in the last line of has been omitted.

An important adjunct to the work is the well-chosen list of original papers which is given at the end of the outline for each general subject. While not intended to be exhaustive it is thoroughly representative and includes all that the student could possibly utilize to advantage at this stage of his development.

The volume as a whole is a meritorious contribution from a skillful teacher and is a welcome addition to the histological laboratory.

MICHAEL F. GUYER

The Fauna of Mayfield's Cave. By ARTHUR M. BANTA. Pp. 114, with plates, map of the cave, figures and tables. Published by the Carnegie Institution, Washington, D. C., September, 1907.

Mayfield's Cave is in Monroe County, Indiana, 4.6 miles northwest of Bloomington, the location of the Indiana University. It has often been visited, and its contents have been described in part by Bollman, Hay, Blatchley, Call, Eigenmann and others. What has been admirably done by Arthur M. Banta is to visit it on an average once a week during eight months in all, covering different seasons of the years, 1903, 1904 and 1905, using the strong, steady light of a carbide bicycle lamp, observing all phenomena, noting the temperature and air currents, and in particular collecting all varieties of animal life for detailed study with the facilities afforded by the laboratory of the university and the expert aid of C. H. Eigenmann. Contours for the cave map are by J. W. Beede, and the photographs are by E. R. Cummings. Full recognition of work done by others is made in the introduction, and in a bibliography mentioning more than 130 works and papers consulted.

Mayfield's Cave is only a fourth of a mile long, is from 6 to 20 feet wide, and is nowhere more than 12 feet high, while many passages are mere crawl-ways. The roof is usually flat and hard limestone, with small domes here and there. The floor is strewn with large and small fragments of stone, with patches of gravel or soil, and occasional banks

and mounds of earth. The excavation is in the Mitchell limestone of the upper Subcarboniferous. The entrance is in a low bluff at the head of a ravine once a part of the cave. There are sink-holes without and springs within, and in winter and spring a cave stream flows through, which ceases to flow in summer, leaving detached pools, parts of the channel remaining moist and other parts being quite dry. The temperature of the earth tends to counteract that of the air currents from without, bringing the average to about 11.9° C., equalling the mean temperature of the region.

Cavern fauna depend on an irregular food-supply and lead a precarious life. Flowing water brings in algae, worms, insects, seeds and other material; mammals and human visitors leave various reminders; and fungus grows abundantly on decaying organic matter. Dry parts were poor collecting ground, while better results were had in moist localities. Most cave animals are scavengers. Some are strays, or accidental visitors; others visit voluntarily; while true cavernicola are classified as temporary, permanent and exclusive residents—the latter never found elsewhere. Banta also classifies them in their relation to daylight, twilight and darkness.

Sixty-six pages are devoted to detailed scientific descriptions of the fauna of Mayfield's Cave, under the heads of Mammalia, Pisces, Insecta, Myriopoda, Arachnida, Crustacea, Annelida, Mollusca and Turbellaria. Six pages are filled by comparative tables of species known to exist in Indiana caves as compared with those found in this single cave; the sum total being 138 species, 110 of which exist in Mayfield's Cave. This is certainly remarkable.

Of true cave fauna the most space is allotted to the blind fish (*Amblyopsis spelæus*, DeKay) concerning which curious experiments were made as to its habits, anatomy and its food as determined by inspecting the contents of the stomach. Two varieties of cave crawfish were found (*Cambarus pellucidus*, Packard, and *Cambarus pellucidus festii*, Hay); the distinction being the presence or the absence of spines. To the cave-

hunter these and other descriptions of strange and unusual forms of life are fascinating.

Several pages are occupied by general observations, with an interesting discussion of the origin of cave life. The latter is treated under three questions: (1) How did these animals get into the caves? (2) What was their condition when they entered? (3) How have they reached their present state? Answering these inquiries the author argues that cave animals originated from outside forms, being predetermined to such cave conditions as suited them; that, at first, they differed slightly from similar forms, but were better adapted than they for subterranean existence; and that they reached their present condition by gradual adjustment to environment, modified by cumulative variations due to heredity.

Taking the monograph as a whole, Mr. Banta is to be congratulated on having given a most commendable example of what can be done by an exhaustive study of a small cavern, and on having thus made a valuable contribution to scientific literature.

HORACE C. HOVEY

SCIENTIFIC JOURNALS AND ARTICLES

Terrestrial Magnetism and Atmospheric Electricity for March contains the following articles: "L'Observatoire Magnétique de Zikawei," by J. de Moidrey; "Carnegie Institution Comparisons of Magnetic Standards during 1908," by J. A. Fleming and J. C. Pearson; "The Carnegie Institution Marine Collimating Compass," by W. J. Peters; "Some Problems in Radioactivity," by A. S. Eve; "Peculiar Magnetic Disturbances in December, 1908," by D. L. Hazard.

The American Naturalist for March contains the papers read at the Darwin Memorial Session of the Baltimore meeting of the Botanical Society of America, held December 29. These papers are: "Darwin as a Naturalist: Darwin's Work on Cross Pollination in Plants," by William Trelease; "Darwin's Influence upon Plant Geography and Ecology," by Frederic C. Clements, and "Darwin's Work on Movement in Plants," by Herbert Maule Richards. In addition there is

"An Examination of Darwin's 'Origin of Species' in the Light of Recent Observations and Experiments," by Edwin Linton. Edward M. East discusses "The Distinction Between Development and Heredity in Inbreeding," and T. H. Morgan describes some results of "Breeding Experiments with Rats," the species being *Mus rattus*, *M. alexandrinus* and *M. decumanus*. Among the "Shorter Articles" is a note by Roy L. Moodie, stating that in parts of the Niobrara River the chub, *Semotilus*, has acquired the habit of feeding on the horn fly that infests cattle, follows up the cattle and captures flies by jumping and picking them from the animal's sides.

Bird-Lore for January-February contains articles on "The Hollow Tree," by Ernest T. Seton; "The Feud of the Crows and the Owl," by Frank M. Chapman; "Birds seen in Prospect Park, Brooklyn," by Kate P. and E. W. Victor; "Notes on Pacific Coast Shore Birds," by John T. Nichols, and the eighth and last paper on "The Migration of Flycatchers," by W. W. Cooke. The Ninth Christmas Bird Census gives the results of observations from a large number of localities and the "Report of Audubon Societies" records the painful fact that two Audubon wardens have been brutally murdered. This illustrates the character of some of the men engaged in "the feather business." It used to be said that each elephant tusk cost the lives of three men and we await statistics on aigrettes.

In the *American Museum Journal* for February Roy C. Andrews describes "A Summer with the Pacific Coast Whales," illustrated with some remarkable views from life. E. O. Hovey tells of "St. Pierre and Mt. Pelé in 1908," giving some illustrations showing how rapidly vegetation is springing up over the region devastated by the eruption of 1902. New exhibits have been arranged illustrating the industries of the California Indians, and it is noted that the museum has acquired the Waters collection of Fiji objects.

On February 28 a Brazilian tapir was born at the National Zoological Park, Washington, D. C., making the fifth of this species that.

has been born there. The period of gestation was 401 days; in another instance it was 395 days. The little tapirs have been strong and were raised with comparatively little trouble.

NOTES ON ENTOMOLOGY

THREE more volumes have been issued by the Indian government in the series "The Fauna of British India." Two are on the Coleoptera. Volume I. is on the Cerambycidae, by C. J. Gahan (329 pp., 107 figs.), and deals with nearly one half of the longicorn beetles of India. They are arranged in four subfamilies—Cerambycinae, Lepturinae, Diatiniinae and Prioninae. Nearly 400 species are described. Vol. II. (Coleoptera), on the Chrysomelidae, is by the late Martin Jacoby (584 pp., 172 figs., 2 colored plates). He arranges the forms in five divisions: Eupodes, Cyclica, Camplosomes, Trichostomes and Cryptostomes. The species of the last two divisions are not treated in this volume; the Trichostomes include the Halticinae and the Galerucinae. Over 900 species are described, many of which are new. Volume IV. of the Rhynchocha (Homoptera and appendix, 501 pp., 282 figs.) is by Dr. Distant. It contains the families Membracidae, Cercopidae and Jassidae; the appendix is mostly on the Pentatomidae. In this volume 665 species are described, bringing the total number of Hemiptera described from India up to 2,768.

MR. EDWARD CONNOLD has published on the British oak galls a companion volume to his work on British vegetable galls.¹ There are chapters on the growth of galls, characters and habits of the Cynipidae, the British oak, and collecting and mounting oak galls. There is, under each species, a succinct statement comprising the English name of the gall, the position of the gall, the manner of growth, color, size, time of year, whether with one or many larvae, where larva pupates, time of issuance of fly and parasites and inquilines. The insects are not described. Fifty-four galls of Cynipidae are treated, and two of other insects. The plates are photographs of

¹ "British Oak Galls," London (Adlard & Son), pp. 170, 68 plates, 1908.

the various galls, often showing much variation in shape.

MR. R. E. TURNER has completed a revision of the Australian species of a peculiar family of Hymenoptera, the Thynnidae.² This family is extremely abundant in Australia, about 400 species being known, over 120 of which are described as new by Mr. Turner. Very little is as yet known of their life history; a few bred from underground pupae of Lepidoptera or Hymenoptera. The author severely criticizes the classification of Ashmead, but adopts most of the genera of Guérin and Westwood. The characters at present used for the genera are found mostly in the sexual organs; a better classification must await the discovery of characters associating the sexes. Mr. Turner excludes from this family the genus *Anthobosca*, which he considers more related to *Myzine*. With the exception of the genus *Ælurus* the South American Thynnidae are of different genera than the Australian.

PROFESSOR WHEELER has written a most interesting comparative study of the ants of Europe and North America.³ He shows that there are fully twice as many kinds of ants in the United States as in Europe. In both countries the ant-fauna is composed of two elements, the boreal and the tropical. The former is very similar in the two regions, but the latter is very divergent, owing to different origins. The difference in nidification of similar ants in Europe and North America is considered due to the amount of sunshine; and it is shown that nests are more abundant in the interior of our country than in the eastern states. There is a summary of the fossil ants of the two countries; a chapter on the parasitic ants of Europe and on the myrmecophilous insects.

MR. W. SCHULTZE has an interesting article on the young of certain leaf-beetles of the

family Cassididae.* Many larvæ of these beetles have peculiar lateral expansions of the body, and a long spiny or bristly tail, which accumulates excrement and cast-skins, and is recurved over the body. When disturbed the larvæ erect and wave these tails. He concludes that these structures are used principally as a protection against parasitic enemies. The eggs are enclosed in a case, frequently one in each case, and these cases are often covered with excrement.

MR. H. S. SMITH has published a most useful work on the Hymenoptera of Nebraska,[†] a synoptic and descriptive catalogue of the Sphegoidea of that state. There are tables to the genera and species, and descriptions of fifteen new forms; altogether over 200 species are recorded from the state. It is hoped that some eastern hymenopterists will follow the example.

PROFESSOR E. B. POULTON has published a detailed museum study of our butterflies of the genus *Limenitis*,[‡] tending to show the influence of *Anosia plexippus* and *Danaida berenice* upon *L. archippus*, and its varieties. He also considers that *L. californica* is the model of *L. lorquini*. Although he brings out many interesting points about coloration and pattern, one can not fail to notice the paucity of field observations which alone are of determining importance in these matters. The author considers that *Papilio philenor* is mimicked by three other species of the genus—*P. troilus*, *P. asterius* (female) and *P. glaucus* (female), which would hardly be suspected by any one familiar with these butterflies in the field.

MR. W. LUNDBECK has published the second part of his book on Danish diptera.[§] As with

* "Life Histories of some Philippine Cassididae," *Phil. Journ. Sci.*, III., pp. 261-271, 6 pls. 1908.

the preceding part, this is a most excellent treatment of the subject. The structural characters are given in great detail; there is a good account of habits and life-history; and under the Asilidae are numerous records of their prey, showing that there is no mimicry of their prey by these ferocious flies. Although the species known from Denmark are very few, the author's treatment of the genera and families is so full as to make the work a most useful one to the American dipterist.

ATTENTION should also be called to the recent catalogue of Argentine Diptera by Dr. J. Brèthes.[¶] He lists the flies of Argentina, Patagonia, Uruguay and Paraguay, 650 species in all; mostly in the Asilidae and Syrphidae. There are 23 species of mosquitoes.

SPECIAL ARTICLES

CONCERNING THE EXISTENCE OF NON-NITRIFYING SOILS

It is believed by agricultural specialists as well as by bacteriologists that soils generally have the power to convert organic or ammoniacal nitrogen into nitrate nitrogen, i. e., to nitrify. Nitrifying organisms are supposed to abound to such an extent that any stratum not possessing them would soon become inoculated with them by air, soil, manure, water or other means.¹

Filter beds, originally non-nitrifying, soon become vigorous nitrifiers without inoculation; sewage nitrifies freely in running streams; nitrate as saltpeter is of almost universal natural occurrence. A surface soil which can not nitrify would be regarded as a rare anomaly, therefore, and that many such non-nitrifying soils exist, could not be expected from the generally assumed conditions.

During our work of the past few years, we have, however, been repeatedly confronted with the fact that many of our soils do not nitrify. The first evidence of the existence of non-

¶ "Catalogo de los Dipteros de las Republicas del Plata," *Anales Mus. Nac. Buenos Aires* (3), IX., pp. 277-305, 1908.

¹ Le Far, "Handbuch der Technischen Mykologie," III., 147.

nitrifying soils was afforded in 1908 during an attempt of one of us to demonstrate nitrification to a class in bacteriology after the usual laboratory manner.* The attempt resulted in a complete failure to secure nitrification. This observation was confirmed by the other at a later time while working independently with other soils. This is noted on page 14 of the report of the North Carolina Agricultural Experiment Station, 1906-7. Since that time, in connection with our studies in nitrification, many samples of soils have been tested for nitrifying power with the result that a large majority of the soils of this region are found to be devoid of this power. The numbers of the soils tested, dates, mode of test, whether in soil or in solution, and the results, are given in the following table.

The tests in solutions were made by the usual method of placing from 0.2 g. (Ashby's Method) to 5 or 10 g. of the soil to be tested into an ammoniacal solution such as that of Omelianski, Wiley or Ashby.

Tests in soil were made by adding nitrogenous material, organic or ammoniacal, to the live soil or by sterilizing the soil, adding the nitrogen, then inoculating with a suspension of the soil to be tested, incubating, shaking with water, filtering, clarifying and analyzing.

Soils which are reported here as negative did not give enough nitrate or nitrite to respond to the diphenylamine test.

SAMPLES OF LOCAL SOILS

29 per cent. nitrifiers.

71 per cent. non-nitrifiers.

LOCAL SOILS

37 per cent. nitrifiers.

63 per cent. non-nitrifiers.

It is seen that of the 62 local samples tested in soil culture, 44, or 71 per cent., failed to nitrify, 18, or only 29 per cent., nitrified; of the 40 different local soils tested 15, or 37 per cent., nitrified while 25, or 63 per cent., failed to nitrify, even though soils which sometimes nitrified slightly and sometimes failed, as Nos. 1783 and 1746, are recorded for this purpose as nitrifying soils.

^a Tested at least twelve times and never failed to nitrify but once.

These soils, with the exception of Nos. 1866, 1867, 1870 and 1871, are normal agricultural soils mostly from within a mile of the farm of the North Carolina Agricultural Experiment Station and are normally productive though not to be classed as rich soils. Nos. 1866 and 1867 are soils from the college green house. Nos. 1870 and 1871 are from commercial green houses of Raleigh.

For comparison, samples of soil were secured from New Jersey through Jacob Lipman, Washington, D. C., from Karl Kellerman, Michigan from W. S. Sayer and Wisconsin from H. L. Russell. It was requested that soils most promising as to nitrifying power be sent. It is seen from the following table that positive results were secured with each of these soils.

Soil	Date of Sampling	Results in:	
		Soil	Solutions
N. J. (H.)	September 28, 1908	+	+
N. J. (R. S.)	September 28, 1908	+	+
D. C. soil	September 28, 1908	+	+
Mich.	October 1, 1908	+	+
Wis.	October 1, 1908	+	+

The positive response of all of these soils and of our own green-house soil serves to doubly emphasize the fact that many of the soils here reported are really lacking in nitrifying power.

Further study of the quantitative results would emphasize still more the differences, since in many instances the soils which we have reported positively gave only a trifling amount of nitrate as compared with soils which are in vigorous nitrifying condition, i. e., most of the soils which we report here as nitrifiers are, with the exception of Nos. 1866 and 1867, very poor nitrifiers as compared with 1866 or with the soils sent to us from distant sources.

While these data include various soils at various times of the year and under diverse climatic conditions, it is, of course, possible that some of the soils here recorded as non-nitrifiers would have induced nitrification if tested at some other time of the year; indeed there is positive evidence that in some in-

stances soils change to a very marked extent in nitrifying power, but inasmuch as the tests here reported cover, in many instances, the period of crop production, their agricultural bearing would not be materially altered.

It is obvious that the absence of nitrifying power is a bacteriological condition that must be reckoned with in soil study. Upon its significance we are by no means ready to pronounce.

NORTH CAROLINA AGRICULTURAL

EXPERIMENT STATION,

WEST RALEIGH, N. C.,

December 8, 1908

THE AMERICAN ASSOCIATION FOR THE
ADVANCEMENT OF SCIENCE
ANTHROPOLOGY AT THE BALTIMORE
MEETING

THE joint meeting of Section H of the American Association and the American Folk-Lore Society was held at the Maryland Institute, Baltimore, December 28-31, 1908.

MEETINGS OF THE SECTIONAL COMMITTEE

In the absence of Professor R. S. Woodworth, vice-president of the section, Professor Boas, retiring vice-president, acted as chairman of the sectional committee. Officers of the Baltimore meeting were nominated as follows:

Member of the Council—B. T. B. Hyde.

Member of the General Committee—G. G. MacCurdy.

Sectional offices were filled by the nomination of Professor William H. Holmes, Washington, D. C., as vice-president for the ensuing year; Dr. George Grant MacCurdy, New Haven, Conn., secretary for five years; and Dr. Geo. A. Dorsey, member of the sectional committee, to serve five years. These candidates were later elected by the association in general committee. Professor W. H. Holmes was also elected president and Dr. George Grant MacCurdy reelected secretary of the American Anthropological Association, the proceedings of which are printed in the *American Anthropologist* for January-March, 1909.

ADDRESSES AND PAPERS

The address of the retiring vice-president, Professor Franz Boas, was on "Race Problems in America." "The Mythology of the Central and

"Eastern Algonkins" was the subject of Professor Roland B. Dixon's presidential address before the American Folk-Lore Society. It will be printed in the first number of the *Folk-Lore Journal* for the current year.

The reports of several standing committees of the American Anthropological Association were of such general interest as to be in the nature of papers. That of the committee on archeological nomenclature, Dr. Charles Peabody, chairman, was ordered to be printed in full as a report of progress, as follows:

The following report has been prepared by Professor John H. Wright, Mr. J. D. McGuire, Mr. F. W. Hodge, Mr. W. K. Moorehead and Dr. C. Peabody, chairman. The recent illness and death of Professor Wright deprived the committee of his advice and suggestion during the final drafting; with this exception the report is unanimous.

To the President and Members of the American Anthropological Association:

The committee on nomenclature of specimens has the honor of submitting the following report; it covers only certain divisions of objects in clay and of objects in stone; the departments referred to them to the committee to be peculiarly suited to a rigid examination resulting in definition, classification and naming.

In all the object of the committee has been to reduce everything to its lowest terms, to use English words, if possible, and words that shall be perfectly clear in denotation to scholars at home and abroad, and to adhere as closely as may be to classifications already made standard.

As has been well said, the difficulty in classification and nomenclature comes from our lack of complete and detailed knowledge.

The classifications here offered and the definitions here proposed in some detail are based, so far as is possible, on form alone. It is, of course, taken as an axiom that a classification based on form assumes no theory of the development, interrelation or conventionalization of forms or types in any manner whatsoever; it has been the particular aim of the committee to avoid or get rid of those classes and names that are based on uses assumed but not universally proved for certain specimens.

Should the attempt meet with the favor of the members of the association, it should be possible at a future date to apply the same principles to a detailed examination of other stone specimens and to specimens in shell, basketry and textiles, so far as has not been already done.

ARTICLES IN CLAY

Simple vessels in clay may be presumed to cover all forms except eccentric or conventionalized (*i. e.*, animal-shaped) forms, on the one hand, and discs and pipes on the other.
